CONTENTS.

THE CULINARY OR KITCHEN GARDEN.

	PAGE
INTRODUCTORY REMARKS,	3
§ 1. SKETCH OF THE HISTORY OF CULINARY VEGETABLES,	3
2. DISPOSITION OF THE CROPS IN THE KITCHEN GARDEN,	7
3. THE QUANTITIES OF SEEDS AND ROOTS NECESSARY TO CROP A GARDEN,	8
4. ROTATION OF CROPS,	12
5. TRANSPLANTING CULINARY ESCULENTS,	24
6. PROPOSED ARRANGEMENT,	26
 CHAPTER I.—ALLIACEOUS PLANTS,	 27
§ 1. THE SHALLOT,	27
2. GARLIC,	29
3. ROCAMBOLE,	30
4. THE ONION,	<i>ib.</i>
5. THE LEEK,	44
6. THE CHIVE,	47
 CHAPTER II.—LEGUMINOUS PLANTS, OR THE PULSE TRIBE,	 48
§ 1. THE PEA,	48
2. THE BEAN,	62
3. THE KIDNEY OR FRENCH BEAN,	71
4. THE SCARLET RUNNER,	78
 CHAPTER III.—BRASSICACEOUS PLANTS, OR THE CABBAGE TRIBE,	 81
§ 1. THE CABBAGE,	81
2. THE PORTUGAL CABBAGE,	90
3. RED CABBAGE,	<i>ib.</i>
4. BRUSSELS SPROUTS,	91
5. THE BROCCOLI,	92
6. THE SAVOY,	96
7. THE CAULIFLOWER,	98
8. THE SEA-KALE,	103
9. THE BORECOLE,	103
 CHAPTER IV.—ASPARAGINOUS PLANTS,	 117
§ 1. ASPARAGUS,	117
2. THE ALISANDER,	129
3. THE CARDOON,	<i>ib.</i>
4. THE ARTICHOKE,	130
5. THE HOP, &c.,	134

	PAGE
CHAPTER V.—SPINACEOUS PLANTS,	135
§ 1. SPINACH,	135
2. WILD SPINACH,	137
3. FRENCH OR MOUNTAIN SPINACH,	138
4. NEW ZEALAND SPINACH,	<i>ib.</i>
5. GARDEN PATIENCE, &c.,	<i>ib.</i>
6. THE WHITE OR SICILIAN BEET,	139
CHAPTER VI.—ACETARIAEAOUS OR SALAD PLANT,	141
§ 1. CELERY,	141
2. CELERIAO, OR TURNIP-ROOTED CELERY,	150
3. THE LETTUCE,	151
4. ENDIVE,	158
5. SUCCORY,	164
6. DANDELION, TARRAGON, &c.,	166
7. WHITE AND BLACK MUSTARD,	167
8. CRESSES,	168
9. PURSLANE, CHERVIL, &c.	171
10. RAPE, CORN-SALAD, &c.,	<i>ib.</i>
11. THE RADISH,	172
CHAPTER VII.—ESCULENT-ROOTED PLANTS,	176
§ 1. THE CARROT,	176
2. THE TURNIP,	183
3. THE POTATO,	199
4. THE JERUSALEM ARTICHOKE,	223
5. RED BEET,	226
6. SALSIFY, SKIRRET, &c.,	228
7. THE PARSNIP,	229
CHAPTER VIII.—OLERACEOUS PLANTS, OR POT-HERBS, COMPRISING SUCH AS ARE USED FOR GARNISHING AND SEASONING,	232
§ 1. PARSLEY,	232
2. DILL, BORAGE, &c.,	234
3. SAGE, BALM, MINT, &c.,	235
4. BASIL, SAVORY, &c.,	237
CHAPTER IX.—MEDICINAL PLANTS,	241
CHAPTER X.—EDIBLE FUNGI,	243
§ 1. THE MUSHROOM,	243
2. THE MOREL,	252
3. THE TRUFFLE,	253
CHAPTER XI.—MISCELLANEOUS VEGETABLES,	256
§ 1. RHUBARB,	256
2. THE TOMATO AND EGG-PLANT,	258
3. THE GOURD AND PUMPKIN,	259
4. CAPSICUM,	260
5. ROSEMARY AND LAVENDER,	<i>ib.</i>
6. THE HORSE-RADISH,	261
CHAPTER XII.—SOILS,	263
§ 1. THEIR ORIGIN AND NOMENCLATURE,	263
2. DETERMINATION OF THEIR NATURE. &c.,	270
3. THEIR IMPROVEMENT,	277
4. WATERING,	284

ADVERTISEMENT.

IN presenting to the public the first part of the PRACTICAL or CULTURAL volume of THE BOOK OF THE GARDEN, we have only a few remarks to premise as to the general plan of arrangement we have employed, and the reasons which have induced us to adopt an arrangement which is, to a great extent, a departure from that hitherto followed in similar books.

Works on Practical Gardening have, for the most part, been arranged in the calender form, no doubt with a view to render them, in the estimation of their authors, more convenient for reference. There are, however, objections to this mode of arrangement, which we think may be avoided by adopting the *sectional* or *separate* garden division, as the operations in any of these departments may be carried on irrespective of the others—a mode of culture which is, in fact, practised in our largest and best-managed establishments, in all of which the subdivision of labour is found to be admirably adapted for facilitating the multifarious operations of the whole. Besides, some people have a predilection for one of these departments more than for another, and many are content with one of them only.

We had hoped that a seasonal arrangement might have been adopted, and that it would have combined all the advantages of the calender form, and have avoided its principal defects. The attempt to carry out this scheme has, however, shown us that it inevitably involved a want of connection and a degree of confusion, which could not be otherwise than most embarrassing to the reader, while it necessitated an amount of repetition which would have made it impossible to comprise the cultural department of the garden in a single volume, without sacrificing that minuteness of detail which is essential to the highest value of such a work.

By the mode of arrangement we have finally resolved on, the reader will more readily find the information he seeks; each subject assumes a more connected form when treated on as a whole, than if it were referred

to in different places; and the necessity for frequent reference and much repetition is wholly done away. On these grounds we think the advantage will be sufficiently apparent of treating on the operations of the KITCHEN OR CULINARY GARDEN, the HARDY FRUIT GARDEN, the FORCING GARDEN, and the FLOWER GARDEN, including PLANT-HOUSES and PLEASURE GROUNDS, &c., as distinct in themselves.

In discussing the various subjects which collectively constitute any of these general divisions, we have adopted a mode of arrangement which we believe to be as complete as is attainable;—our great object being to systematise the whole, by bringing together, in our accounts of their culture, such productions as have a natural affinity to each other.

As regards the descriptive lists of the most approved *Fruits, Vegetables, Flowering Plants, and Ornamental Trees, Shrubs, &c.*, we avail ourselves of the present as a fit opportunity for correcting former lists, and adding those of recent introduction or origin, when of sufficient merit, to the lists of a similar nature which have appeared in practical works such as "THE BOOK OF THE GARDEN" professes to be. This is the more important, because, with the exception of Mr Hogg's excellent work, "British Pomology," which treats on the apple exclusively, there has been no book of a similar description to the present published in Britain since our "Practical Gardener" and "The Orchard," both of which, in this respect, are now very far behind the requirements of the present age. The excellent descriptive "Fruit Catalogue of the London Horticultural Society," and the no less valuable "Orchard," by the late Mr G. Lindley, and "The Fruit Cultivator," by the late Mr Rogers, stand in a similar position to the works already named. The only channels through which the new and improved varieties of *Fruits, Vegetables, and Plants of general interest* have reached the public, (since the "Practical Gardener" was last revised by us, more than twelve years ago,) have been the horticultural periodicals, and the nurserymen's and seedsmen's trade catalogues; although, during this period, more important additions have been made to all of these classes than during any former period of the same extent. These lists, valuable as they certainly have been in making us acquainted with every novelty as it appeared, have, from their nature, scattered the information sought for over a wide extent of volumes and tracts, which renders the task of referring to them expensive and often exceedingly difficult. To these additions we may add the many fine fruits of American origin, and the vast number of new ornamental plants which, at the date of the works referred to, were wholly unknown in this country.

From them, selected lists of such varieties as are suitable to our climate, &c., will be made.

The arrangement of these lists will be as follows :—

The most approved and recently introduced Esculent Seeds and Roots will accompany the articles to which they respectively belong in the Culinary Garden.

The most approved and recently obtained Hardy Fruits will in like manner be found in the Hardy Fruit Garden.

The Tropical Fruits in the Forcing Garden. And

The more rare, choice, and interesting Trees of Ornament, &c., Flowering Plants, &c., will accompany the Flower Garden.

We have given some brief details of the practices of the London market-gardeners, who, it must be admitted, are the best culinary gardeners in the world. This is a subject scarcely hinted at by authors on gardening since the days of Abercrombie, the merits of whose excellent works (we mean the original editions) are mainly owing to the copious details he gave of the market-gardening of his day. As nearly a century has now elapsed since he wrote his first work, and as during that period a corresponding improvement has taken place in that department, as well as in that of private gardening, a work of this kind would be incomplete without a notice of these excellent modes of culture.

Little or nothing has been published concerning the London practice since that time, and private gardeners, in general, know little how things are there managed. There has been a reserve on the part of the former in affording information, and an unwillingness on the side of the latter to undergo the hard work to which they would be subjected, were they to spend a year in a market-garden, rather than two or three loitering about a nursery—too often a tax upon the proprietor, and losing much of their own valuable time. We here allude to young gardeners only, who would acquire a much greater amount of useful information in the general routine of their profession were they to spend a year in a first-rate London market-garden, than they could do in a dozen years, toiling nearly as hard, in very inferior places in the country. We are far from insinuating that a nursery is a bad school for a young gardener; on the contrary, no man can have much pretension to a thorough knowledge of his business, unless he has spent a part of his career in a first-rate establishment of that kind. In it he learns what he could not do in a private garden; he learns the most approved methods of propagation, has many

opportunities of studying the nomenclature of Fruits, of attaining a general knowledge of Plants, and the best modes of taking up and packing Trees, and of becoming acquainted with the new and rarer ornamental and useful Trees and Shrubs, upon which decorative gardening is destined in future so much to depend. In many of these establishments he may obtain some practice in laying out grounds, as nurserymen of high repute are often employed as landscape-gardeners. In fact, every gardener wishing to excel in his profession, should spend a couple of years in such establishments, and one at least in a London market-garden.

To one department of great importance, both to the practical gardener and the amateur, and which has hitherto hardly received the attention it merits in practical works—that of the diseases, insects, and other enemies, to the attacks of which the various products of the garden are liable—especial attention has been paid. Full descriptions have been given of these from the best authorities, supplemented by actual observation, and also full details of the most approved methods of prevention and cure; while the insects in particular have been much more extensively figured than has, it is believed, ever before been done in any single work, and this on a scale and with a minuteness which will make the identification of them easy even to a comparatively superficial observer.

We have thought it expedient to give the European names of culinary vegetables and fruits, more especially the former, on account of our increasing intercourse with the Continent, and the quantities of seeds which are yearly brought or sent into this country, and often put into the hands of those unacquainted with the language in which the names are given. Readers of such popular Continental works as the “*Bon Jardinier*,” the “*Utrechtsche Hovinier*,” “*Garten Zietung*,” “*Verstandige Gartner*,” and similar books on gardening, may be assisted by a reference to the paragraph *General Remarks* at the end of each section.

Throughout the whole of this department of our subject, it will be our special aim to enter into all necessary minuteness of detail; to avoid all technicalities of term, or, wherever we are compelled to employ these, to append full explanations of them; and, in short, to make the “*BOOK OF THE GARDEN*,” as to its cultural department, so precise and complete in all its directions, that it may suffice to the tyro as his guide, from the most rudimental operations of gardening onward, and render the amateur in a great degree independent of other assistance; while, to the experienced gardener, we trust it will be found the best and most practical work of reference extant.

THE
BOOK OF THE GARDEN

CULTURAL

THE

CULINARY OR KITCHEN GARDEN.

INTRODUCTORY REMARKS.

§ 1.—SKETCH OF THE HISTORY OF
CULINARY VEGETABLES.

THE culinary or kitchen garden, (*jardin potager* of the French,) with all its varied productions, if not the most ornamental, will be admitted to be the most useful of all the departments of gardening. Many of the crops cultivated in those of the present day were raised, and we have no great right to suppose otherwise than that they were so to a very creditable extent, although upon much less scientific principles, soon after the Deluge, if not prior to that epoch. They are early mentioned in the histories of the nations of the greatest antiquity. The onion, the leek, the cucumber, and the garlic, were in extensive cultivation in Egypt long before the exodus of the children of Israel; and herbs for seasoning cooked dishes were also well known at an equally early period. Of the means employed in their production we have no records left earlier than the date of the foundation of Rome. Soon after that period we find the environs of that city in a state of cultivation much like what exists around large towns and cities of our own time—namely, as market-gardens, in which were cultivated many of the culinary vegetables such gardens at present produce. One important difference, however, may be remarked—the culinary gardens around ancient Rome were cultivated by the chief men, who were also the proprietors, and they themselves wrought the ground with their

own hands; and hence several of the most celebrated families—the Pisones, the Cicerones, the Fabii, the Lentuli, &c.—derived their patronymics from ancestors who had distinguished themselves in the cultivation of culinary vegetables. Thus, *Pisum*, a Pea; *Cicer*, a Chick-pea; *Faba*, a Bean; *Lentulus*, a Lentil, &c.

Nor did some of their greatest historians consider it beneath their literary dignity to record many interesting hints regarding the modes of culture employed. Cato, Varro, Columella, Palladius, Pliny, Virgil, Martial, &c., have left us quite enough, in those portions of their writings which have been handed down to us, to satisfy us that the culture of culinary vegetables was well understood and fully appreciated in their days. The former of these has left us in detail the Roman mode of cultivating asparagus, which was the last vegetable written upon by him, and may serve as a pretty good example of ancient Roman gardening. “You must work a spot that is moist, or which has richness and depth of soil. Make the beds so that you may be able to clean and weed them on each side; let there be a distance of half a foot between the plants. Set in the seed, two or three in a place, in a straight line, cover with mould, then scatter some compost over the beds. At the vernal equinox, when the plants come up, weed often, and take care that the asparagus is not plucked up with the weeds. The year you plant them, cover them with straw during the winter, that

they may not be killed. In the beginning of the spring after, dress and weed them. The third year after you have sown them, burn the haulm in the beginning of the spring. Do not weed them before the plants come up, that you may not hurt the stools. The third or fourth year you may pluck them close by the root; if you break them off, they yield side-shoots, and some will die. You may take them until they run to seed. The seed is ripe in autumn. When you have gathered the seed, burn the haulm, and, when the plants begin to shoot, weed and manure. After eight or nine years, when the beds are old, lay out a spot, work and manure it well, then make drills where you may plant some roots; set them well apart that you may dig between them. Take care that they are not injured. Carry as much sheep's dung as you can on the beds: it is best for this purpose; other manures produce weeds."

The globe artichoke is said by Pliny, book xix. chap. viii., to have been more esteemed, and to have obtained a higher price, than any other garden herb. He also informs us that the commoners of Rome were prohibited by an arbitrary law from eating this vegetable. He, at the same time, censures his countrymen for their vanity and prodigality as regards the serving up such things to their tables as the very asses and other beasts refuse to eat, for fear of pricking their lips. The same writer, book xix. chap. iv., tells us that asparagus, which formerly grew wild, was, in his time, carefully cultivated in gardens, particularly at Ravenna, where the heads were so large that three of them would weigh a pound.

Basil, which stands now so high in the gastronomic art, that a new-made alderman would spurn a basin of turtle if not seasoned with it, was condemned by Chrysippus, more than two hundred years before Christ, as an enemy to the sight and a robber of the wits. Diodorus and Hollerus entertained equally superstitious notions regarding it. Philistis, Plistonius, and others, extolled its virtues, and recommended it as strongly as it had been formerly condemned. Pliny says, the Romans sowed the seeds of this plant with maledictions and ill words, believing that the more it was cursed the better it

would prosper; and when they wished for a crop, they trod it down with their feet, and prayed to the gods that it might not vegetate!

The bean was cultivated both by the earlier Greeks and by the Athenians, who offered them as oblations to the gods—a practice, according to Pliny, afterwards followed by the Romans; and Lemprière states that bacon was added to the beans in the offerings to Carna—not, as he says, so much to gratify the palate of the goddess, as to represent the simplicity of their ancestors. The beet was highly prized by the Greeks, who used to offer it on silver to Apollo at Delphos. They used also to eat the leaves in preference to lettuce, and, by laying a small weight on the plant, they blanched it, much as gardeners of the present day lay a tile over endive plants for a like purpose. Pliny says, beets are, of all garden herbs, the lightest roots; that they are eaten, as well as the leaves, with lentils and beans; and that the best way to eat them is with mustard, to give a taste to their dull flatness. So highly was the cabbage esteemed by the ancients, that two of their leading physicians each wrote a book on the properties of the plant. Phillips tells us that the ancient Romans, having banished physicians out of their territories, preserved their health for six hundred years, and soothed their infirmities, by the use of this vegetable alone. Pliny goes to great length on the use and culture of the cabbage, which, he says, may be cut as coleworts at all times of the year; so may they be sown and set all the year through; but he adds that the most appropriate season is after the autumnal equinox; and also remarks that, after the first cutting, they yield abundance of excellent tops. Powdered nitre, sea-weed, and asses' dung, were used as a fitting manure for them. "There are," Pliny remarks, "many kinds of coleworts at Rome," and amongst them, one received in his time "from the vale of Aricia, with an exceedingly great head and an infinite number of leaves, which gather round and close together"—probably the first type of our hearting cabbage, for those previously described by him appear to have been open-hearted or true coleworts. He afterwards, however, says, "there are some coles which

stretch out into a round shape, others extend in breadth, and are very full of fleshy brawns, and some possess heads twelve inches thick." He also remarks, that all the varieties eat sweeter from being touched with the frost, an opinion prevalent at the present day. In the Roman culture we find that the sprouts were planted as well as the young plants—a *discovery* made a few years since, and recorded in one of our most costly horticultural works, and described nearly as Columella did many hundred years ago.

Fennel was cultivated largely by the Romans as a garden herb, and so much used in the kitchen that there were few meats seasoned or vinegar sauces served up without it. "A good housewife," says Pliny, "will go into her herb-garden instead of a spice-shop for her seasonings, and thus preserve the health of her family by saving her purse."

From an anecdote related by Herodotus, in connection with the murder of Smerdis by his brother Cambyses, it is quite evident that lettuces were served at the royal tables of the Persian kings five hundred and fifty years before Christ. The ancient Romans, however, appear to have known only one sort, which Pliny describes as a black variety. Suspicion prevailed of their having a deleterious effect; but, after Antonius Musa cured the Emperor Augustus Cæsar by means of this plant, that suspicion vanished, and, as Pliny says, men began to devise means of growing them at all seasons of the year. The variety of lettuce cultivated by the Greeks is stated to have grown "high and large." Those employed by the Romans in the days of Pliny were the purple sort, with a large root, the Egyptian, Cilician, Cappadocian, &c. Great pains, he says, were taken to make them cabbage, and they were earthed up with sea-sand to blanch them and give them heart. The white lettuce was noticed as being the least hardy even in that mild climate.

Salads were much esteemed amongst the ancients, and even poets sang their praises. Ovid, in his "Philemon and Baucis," says—

"A garden-salad was the third supply,
Of endive, radishes, and succory."

VOL. II.

And Columella also thus notices the endive—

"And endives, which the blunted palate please."

The endive is said by modern botanists to be a native of the East Indies. This would lead us to believe them little acquainted with European historical authors; for, besides Ovid and Columella, Pliny also mentions endive in the eighth chapter of his twentieth book. Horace alludes to the plant under the name of *cicorea*, in lib. i. ode 31; Virgil makes special mention of the marigold in the second eclogue of his "Bucolics;" and Catullus thus notices the marjoram, in the "Epithalamium of Julia and Manlius"—

"Bind your brows with the sweet-smelling marjoram."

Mint is equally honoured by Ovid's notice of it, from which we learn that the humbler classes used to perfume their tables by rubbing the plant upon them before serving their supper; and so highly was mint thought of at Rome, that Pliny says, "you will not see a husbandman's board in the country, but all the meats, from one end to the other, are seasoned with mint." The humble creeping Penny Royal formed the subject of a consultation of physicians held in Pliny's chamber, the result of which was, that they agreed that a chaplet of this plant was, without comparison, far better for giddiness and swimming of the head than one of roses. We have met with no account of the cultivation of the mushroom in the authors of antiquity, but that they were in extensive use is quite evident, had we no better authority than the circumstance of one of them, the *Agaricus Cæsaræus* having been made the vehicle of poison by Agrippina for her husband, Tiberius Claudius. That they were as highly prized amongst the epicures of ancient Rome as they are by those of modern London, is evident from what Pliny says of them, in his 6th book, chap. 8, "the last device of our epicures to sharpen their appetites, and tempt them to eat inordinately, is the cooking of mushrooms;" and, in the 23d chap. of his 22d book, he adds, "there are some dainty wantons of such fine taste, and who study their appetite to such excess, that they dress mushrooms with their own hands, that they may feed on the

B

odour during the time they are handling and preparing their food."

Mustard must have been cultivated in Syria while our Saviour was upon earth, as it is mentioned in one of His beautiful parables as being the least seed that was sown in the field. The mustard here referred to does not appear, from the circumstance of the size of its seed, to be the mustard of our times. This has led to various conjectures, none of which have much plausibility. The mustard of the present time was cultivated in Rome, in Pliny's time, to the extent of three varieties.

The origin or native country of the well-known onion is unknown. Pliny, in book 20, chap. 5, enumerates all the countries from whence the Greeks as well as the Romans procured different varieties of this root, but declares he could never discover where they ever grew wild. Palladius, a Greek physician, recommends the onion to be sown with savory, in which curious opinion Pliny agrees, observing that onions prosper better when savory is sown with them. It was a current opinion, we should state, in those days, that certain plants had an antipathy to, or a sympathy with, each other. However absurd such an idea may appear to us, we should take into consideration that the opinions of the ancients may not have been faithfully handed down to us, or that their works may admit of a somewhat different construction. "We find," Phillips observes, "that all the plants which they recommend to be sown or planted together are of very opposite natures; and there may be more reason in the system pursued by the ancients than is generally allowed; for plants drawing the same juice from the earth must naturally weaken each other; whereas those requiring different nutriment may, in some degree, assist each other, each feeding on juices that are prejudicial to plants of the other species." In this there is great truth. The garlic was in use at as early a time as the onion; the want of both was lamented by the Israelites in the wilderness. The Egyptians worshipped it, and are said to wish that they may enjoy it in paradise. The Greeks held it in such abhorrence, that those who ate it were regarded as profane. The Romans gave it to their labourers to strengthen them, to their soldiers to excite courage, and fed their

game-cocks on it previous to fighting them. The eschalot (or shallot, as it is often written) is a species of onion, and was well known to both the Greeks and Romans. Pliny states, book 19, chap. 6, that the best leeks were brought from Egypt, and names *Aricia*, now called *Riccìa*, in Italy, as celebrated for them in his time, and says, "it is not long since leeks were brought into great notice and esteem by the Emperor Nero, who used to eat them for several days in every month to clear his voice, eating them with oil only, and abstaining from bread on those leek-eating days," which absurdity led his people to give him the cognomen of *Porrophagus*. Pliny, book 20, chap. 11, informs us that parsley was in great repute in his time, all classes partaking of it largely in their pottage, and that there was not a salad or sauce presented at the table without it. The Emperor Tiberius held parsnips in high repute, and had them annually brought to Rome from Germany, from the neighbourhood of Gelduba on the Rhine, where they were said to have been grown in great perfection. The Greeks sowed their pease in November; the Romans did not plant theirs till the spring.

So highly did the ancient Greeks esteem the radish, that, in offering their oblations to Apollo, they presented turnips in lead, and beet in silver, whereas radishes were presented in beaten gold. The Greeks appear to have been acquainted with three varieties of this plant; and Moschian, one of their chief physicians, wrote a whole book on the radish alone, so highly did he think of it. Pliny observes, that radishes grow best in saline soils, or when they are watered with salt-water; and hence, he says, the radishes of Egypt are better than any in the world, on account of their being there supplied with nitre. He gives some account of the kinds grown at Rome in his day, one of which he describes as being so clear and transparent that one may see through them. The transparent variety of our day has not this property to the same extent. The size also to which the radishes of those days are said to have attained far exceeded those of the present, nor do we think such would be appreciated by our modern radish-eaters. Tragus mentions radishes that weighed 40 lb.;

and Amatus states, he has seen some of 60 lb.; while Matthiöle declares having met with them 100 lb. each. Somewhat in accordance to views recently promulgated in regard to increasing the size of roots, these monster radishes are said to have been produced by carefully taking off the leaves. The ancients used them boiled; the Roman physicians, however, directed them to be eaten raw with salt, as in our modern practice, and that they should be taken in the morning before any other food.

Savory and lavender are recommended by Virgil as fitting plants to be set near bee-hives—

“The verdant lavender must there abound,
There savory shed its pleasant sweets around.”

They were used by the Romans to mix with cool salads, such as lettuce and radishes. Vinegar flavoured with savory and other aromatic herbs was much used by the ancients to dip their animal food in previous to eating, or as we now do mint-sauce, with lamb. Sorrel was cultivated in Pliny's time, as he makes mention of “garden sorrel, or sour dock.” Thyme was imported to Rome from Attica, and cultivated for the sake of bees. Watercress was eaten by the ancients along with lettuce, to counteract the cold nature of that vegetable.

We have above given a cursory view of the ancient history of culinary vegetables. That we have improved in culture, and in the production of superior varieties, is undeniable; but that we have not added very greatly to the number of species is equally apparent. The periods when indigenous vegetables became reclaimed, or brought into a cultivated state, as well as the dates of the introduction of exotic ones, will be found under their respective heads.

§ 2.—DISPOSITION OF THE CROPS IN THE KITCHEN-GARDEN.

A systematic mode of arranging the contents of the kitchen-garden, although no one can doubt the propriety of such a course, has, in the majority of cases (not even excepting some of our very best gardens), been next to disregarded. The plants cultivated rank as either peren-

nials of several years' standing, or as annuals, and some few biennials occupying the same ground only one, or at most two years. We see, therefore, no good reason why two distinct classes of arrangement should not be formed; but as it occurs in practice, as will be hereafter shown, that the annuals and perennials comprising our olitory or sweet herbs are more conveniently cultivated when set apart by themselves, we shall exclude them from our present arrangement, adding, however, the strawberry, gooseberry, currant, and raspberry, which belong properly to the fruit-garden, but are in general cultivated in the quarters of the kitchen-garden. By such an arrangement, a better rotation of crops may be followed out, and the garden made to assume a more methodical appearance. Where, however, sufficient slips of ground surround the main garden, these perennial crops may be therein planted, and, having stood their allotted time, successional plantations of them may be made to occupy one or more of the quarters within the main garden, in extent according to the quantity required to meet the demand. When these are thus removed (which removal, in the case of the gooseberry, currant, and raspberry, should take place at periods of from seven to twelve years), the ground they occupied will be in a very fit state to afford a change of soil to some of the annual crops cultivated during that time on the ground now to be occupied by the others. The perennial crops to which we refer (exclusive of the fruits above) are, asparagus, sea-kale, rhubarb, and globe artichokes. Where the three former are forced upon the taking-up plan, an annual change of soil is attained; and as artichokes and strawberries should be replanted yearly, or in most cases once in two years, this increases the opportunity of carrying out rotation. No doubt the three first, in good soils, and where they are allowed to come into use at their natural seasons, will last for from seven to twelve years, or even much longer, but we see no advantage in continuing them beyond the last-named period. For these reasons, we would group the gooseberry, currant, and raspberry in a plot by themselves, and not dispose them in the scattered manner

they usually are met with, occupying more room, less conveniently protected, exposed to having their roots mutilated by digging about them, and, last of all, affording by their removal no useful rotation. The other perennial crops may be planted next to them, and, if allowed to remain, either to be forced on the ground, (as is usually done in the case of the sea-kale and rhubarb in particular, and in that of the asparagus occasionally), or to be allowed to come in at their natural season, then the whole quarter may be destroyed at once (presuming a succession is established in that adjoining), and the ground they occupied cropped with annual crops, for which the manurial applications hitherto given will render it exceedingly fit, particularly for carrots, onions, &c., which seldom succeed on newly-manured ground. That, however, occupied with the gooseberries, currants, and raspberries, being less enriched, must now have manure applied to it. The strawberry crop will now, by about the seventh year, have travelled, by yearly changes, to the further side of the adjoining quarter, followed up by the successional crops of sea-kale, asparagus, and rhubarb, and, last of all, by currants, gooseberries, and raspberries. In this way, these crops may be made to circulate round the quarters or divisions of the main garden; and if the changes appear to be too rapid, an occasional shift to the slips may be had recourse to.

No doubt an excellent rotation is afforded, when a portion of these crops is taken up annually for forcing, the ground vacated being next occupied with annual crops; but this rotation, although equally good in principle, is less systematic in appearance.

The extent of ground occupied by any one species of esculent must ever depend on the quantity of the particular sort required to meet the demand. The following is about the proportions: Pease occupy, in general, the largest breadth in most gardens; always so, when the family are resident in the country; somewhat less, when they only arrive about the 1st of August (a very usual period), as crops before that are not required. The cabbage tribe comes next in order, and would occupy the larger space, were it not that the crops for the latter end of winter and

early spring are planted on the ground from which the first crops of pease have been gathered. Turnips would stand next, were it not that asparagus, sea-kale, and rhubarb, to be forced during winter on the taking-up principle, require to be extensively grown, on account of the roots being destroyed when the crop is gathered; and this is more especially the case when a family requires them throughout the winter and in spring from the open ground also. Potatoes would rank next, were it expedient to grow them in gardens (beyond the early crops), which it is not; for, from some hitherto unexplained cause, they never are of so good a quality in richly-manured gardens, as in the less highly manured fields. Carrots, leeks, and onions follow—the former, however, being a precarious crop. Celery and spinach would occupy as large a space as the last, were it not that the latter, particularly for winter crops, which are the principal, is not sown till the latter end of July or beginning of August, on ground from which probably the early crop of pease has been removed. Garden and kidney beans, and scarlet runners, follow—the two latter having a preference, in most gardens, to the former. Parsnips, globe artichoke, and beet are the next in order, followed by parsley, endive, salsify, skirret, scorzonera, and Jerusalem artichokes; garlic, shallot, rocambole, succory, chervil, and all manner of pot and sweet herbs, find a place in the olitory or herb-garden; and lastly, lettuce, of which there is a perpetual sowing and planting, being usually, unless grown upon a very large scale, accommodated with room amongst other crops, as its duration in summer is short—and during winter it is placed in sheltered places, by the bottoms of walls, &c.

§ 3.—THE QUANTITIES OF SEEDS AND ROOTS NECESSARY TO CROP A GARDEN.

The young gardener will find himself, upon taking charge of a garden for the first time, in a much greater dilemma, when about to make up his seed order for the ensuing year, than in any other part of his charge. To order without some certain knowledge of the quantities

required, entails not only an unnecessary expense on the owner, but if the quantities be not properly proportioned to each other, and each in as near a proportion as possible to the quantity of produce required, he will be in a second dilemma, when he finds he has more of one sort than he requires, and too little of some others.

Various estimates have been formed, and scales of quantities drawn out, ever since the days of Gordon of Fountain Bridge, who published his "Pocket Dictionary" in 1774. That great difficulty attends even an approximation to the truth, so as to be of universal application, will be sufficiently evident, when we take into consideration that some families use a greater quantity of vegetables than others; some requiring them all the year over, while others are content to have them at such times as they are produced naturally in the open air. Some prefer more of one sort than of others, and there are many esculents which some reject altogether. Much also depends on whether an English or French cook steers the helm of affairs in the kitchen: the former, we have invariably found, uses the greater quantity; while the latter, while he uses them in less bulk, is far more particular in having them young, and in proper season.

Again, there is the nature of the soil and the situation to be taken into consideration, as well as whether the garden is protected from game, or open to their attacks. With these data all to be taken into account, it is quite clear that only an approximation to the exact quantities can be arrived at, even by the most conversant in those matters; but that approximation is better than none at all. Before, however, stating what we conceive to be the necessary quantities under these circumstances, we must premise a few words of warning to those gentlemen who make up their own seed-lists, and who are always on the look-out for *cheap houses*, and advertised seed sales by auction—in too many cases got up by a set of swindlers, whose chief personal characteristics are a pair of huge *mustaches*, and an affectation of being totally ignorant of the English language. To such we say, Take the responsibility upon yourselves; and when you find no crop forth-

coming, blame neither your gardener nor your soil. The more respectable the firm you purchase from is, the more certain you may be of avoiding disappointment. Besides, you have a remedy against the one; none whatever against the other. The law will afford you protection, and award you full and fair compensation for loss in the one case, but you may whistle for it in the other. Besides, firms of respectability have a character to maintain, of far more importance to them than any gain that could arise out of any fraudulent transaction.

We greatly object to most of the former seed estimates published, because they are in general below the mark; and much as we deprecate thick sowing, still, seeds are now so cheap that it were false economy to have such a deficient supply at first, as to be compelled to re-sow a crop cut off by insects, frost, or other accidents, to which all such crops are liable; or to be without a supply at hand, in the event of the crop being entirely destroyed.

We give below the seed estimate of Gordon, of 1774, to show the quantities he allows, but more particularly to show that many of the vegetables still popular with us were so nearly a century ago.

"A seed bill for a private family, calculated to crop a garden consisting of an acre of ground.—4 lb. early Charlton pease; 4 lb. Nicol's early Hotspur do.; 4 lb. golden early do.; 4 lb. common Hasting, or Essex Reading do.; 4 lb. Turkey Hotspur, or long marrow-fat do.; 4 lb. dwarf marrow-fat do.; 4 lb. Leadman's long dwarf do.; 1 lb. early Mazagan beans; 1 lb. early Lisbon do.; 2 lb. long-podded do.; 4 lb. Tokar do.; 4 lb. Windsor or Turkey do.; $\frac{1}{2}$ lb. Barbary kidney do.; $\frac{1}{2}$ lb. Battersea do.; $\frac{1}{2}$ lb. Strasburg onion; 3 oz. red Spanish do.; 1 oz. silver-skinned do.; 4 oz. London leek; 4 oz. orange carrot; 1 oz. early horn do.; 2 oz. Dutch parsnip; $\frac{1}{2}$ lb. early Dutch turnip; 2 oz. yellow do.; 2 oz. red-topped do.; $\frac{1}{2}$ lb. shallot; $\frac{1}{2}$ lb. garlic; 4 oz. early London short-topped radish; 2 oz. salmon do.; 1 oz. turnip-rooted do.; 1 oz. black Spanish do.; 6 dr. cabbage lettuce; 4 dr. ice or white Cos do.; 2 dr. Silesia do.; 2 dr. tennis-ball do.; 2 dr. brown Dutch do.; 4 oz. curled cress; 2 oz. broad-leaved do.; 4 oz. common do.;

$\frac{1}{2}$ oz. Indian do. ; 2 oz. curled parsley ;
 $\frac{1}{2}$ oz. common do. ; $\frac{1}{2}$ lb. white mustard ;
 $\frac{1}{2}$ oz. curled endive ; 4 dr. Italian celery ;
 4 dr. long green cucumber ; 4 dr. short
 prickly do. ; 2 dr. best melons ; 1 lb.
 round spinach ; $\frac{1}{2}$ lb. prickly do. ; 1 oz.
 French or Mountain do. ; 1 oz. white
 beet ; 1 oz. green do. ; 2 oz. red beet, or
 beet-rave ; $\frac{1}{2}$ oz. cauliflower ; $\frac{1}{2}$ oz. white
 broccoli ; $\frac{1}{2}$ oz. purple do. ; 1 oz. early
 Yorkshire cabbage ; 1 oz. sugar-loaf early
 do. ; $\frac{1}{2}$ oz. red Dutch do. ; 4 oz. late Aln-
 wick do. ; $\frac{1}{2}$ lb. green savoy ; 2 oz. yellow
 do. ; 2 oz. Kilmaurs kale ; 4 oz. scarlet
 beans."

Our own estimate, in a similar case, is
 this ; but as the varieties of cultivated
 vegetables are now so numerous, we shall
 omit specifying them, referring the reader
 to our select lists, which will be found
 appended to each subject, as well as leav-
 ing unnoticed some few kinds not gene-
 rally expected to be found in a garden of
 the limited extent of one acre : Pease, 36
 qts. ; garden beans, 10 qts. ; French or
 kidney beans, 4 qts.—*provided none are
 forced*. Scarlet runners, 2 qts. ; cabbage
 of early sorts, 8 oz. ; savoys, 4 oz. ; Brus-
 sels sprouts, 3 oz. ; cauliflower, 4 oz. ;
 broccoli of sorts, 8 oz. ; borecoles, 4 oz. ;
 red cabbage, 2 oz. ; late or drumhead
 do., 2 oz. ; kohlrabi, 2 oz. ; onions, 12 oz. ;
 carrots, 8 oz.—*if none are forced*. Turnip,
 white sorts, 16 oz. ; yellow do., 6 oz. ;
 celery, 2 oz. ; spinach, 8 qts. ; red beet,
 4 oz. ; yellow do., 2 oz. ; leeks, 4 oz. ;
 parsnips, 4 oz. ; salsify, 2 oz. ; skirret,
 2 oz. ; scorzonera, 2 oz. ; endive, 4 oz. ;
 lettuce, 4 oz. ; radish, 3 pts.—*if none are
 forced*. Mustard, $1\frac{1}{2}$ qts., and cress the
 same—*if neither are forced*. Parsley, 4
 oz.—2 oz. curled, and 2 oz. plain. Of roots,
 early potatoes, $1\frac{1}{2}$ bush. ; of late do., 3
 bush. ; Jerusalem artichokes, 1 pck. ;
 garlic, $\frac{1}{2}$ lb. ; shallots, 2 lb.

It does not, however, *exactly* follow that a
 garden of 20 acres extent requires twenty
 times the quantities shown above ; this,
 however paradoxical it may appear to the
 uninitiated, is well known to the practical
 cultivator. An example may be given in
 the case of a *seed-bed* of cabbage, caulif-
 lower, leeks, &c. A first planting is taken
 from the most forward plants, which, in
 general, are those arising from seed of the
 preceding year, or of those of that year
 most fully matured, compared with less

perfectly ripened seeds, even of the same
 year's growth. They also arise from seed
 of the previous year's production being
 stronger than seeds of one or two year's
 standing, thus producing a very necessary
 succession in the hands of those who know
 how to manage matters rightly ; and, con-
 sequently, the experienced gardener, avail-
 ing himself of the knowledge of which he
 has long been possessed, will and does
 take such plants in succession, as he
 well knows, under favourable circum-
 stances, the stronger plants will come
 first to maturity, or else they will run to
 seed, and be useless. This misfortune is,
 however, made up for in the second plant-
 ing, and this is succeeded by the third.
 In the meanwhile, let us endeavour to
 set aside the too prevalent opinion that
 seed of the previous year's growth *alone*
 should be sown, with some few exceptions.
 Than this a more erroneous notion could
 not, we think, have been driven into the
 craniums of those of our wiseacres, "the
 advocates for new seed." The honest
 seedsman does an act of great kindness,
 and confers an important benefit on his
 customers, when he mixes seeds of 1851,
 1852, and 1853 together ; for, provided
 they have been *well kept*, the advantage in
 the case of many seeds (take the whole of
 the Brassicæ as an example) is very much
 in favour of the purchaser. For our-
 selves, we would not thank any man for
 seeds of cauliflower, broccoli, turnip, &c.,
 of last year's production ; and to avoid
 the chance of disappointment from this,
 we invariably keep by us in stock seeds
 of this natural order, of from two to five
 or six years. Our older gardeners, while
 they have handed down to us volumes of
 rules, have been very sparing in paying us
 the same compliment in regard to reasons.
 We have hardly had one assigned for the
 invariable rule of their carrying their
 cucumber and melon seeds in their
 pockets for months before they com-
 mitted them to the soil. An ancient
 sage says, "there is reason in the boiling
 of an egg ;" so is there in carrying the
 seeds referred to in the warm dry atmo-
 sphere of a pocket. It is in consequence
 of the *genial* heat bringing about a
 state of maturity in the seed, which
 our cold climate, compared with Persia,
 the country of the melon, is incapable
 of doing ; and hence the practice of

keeping such seeds for years, until they, as it were, arrive at maturity in consequence of age, or are brought artificially to that state by the means (or other means similar) above stated, which is correct in principle. In the case of the natural order above referred to (the Brassicæ), seeds of three ages have been found of vast advantage—a circumstance, if we recollect rightly, brought before the public some years ago by Mr Archibald Gorrie, who, in reference to the turnip (and all the Brassicæ may be taken in the same category), says the plants from seeds of the previous year, being stronger, vegetate first, and afford food for the fly, while those from the seed of the year previous to that follow in succession; and if vegetation be going on rapidly, these may escape wholly the attacks of insects; if not, the older seed of all, which vegetates last, is certain to escape, because the fly has had wherewithal to satiate its voracious appetite; and by the time the third in succession comes into leaf, the insects have undergone their transformation. This is also a reason for thick-sowing under peculiar circumstances. Nor is the preservation from the fly all that arises from fully matured seed. If we only take a crop of early Dutch turnip as an example, it will be found that the plants raised from seed of the previous year will be exceedingly prone to run to seed without bulbing; and should they even do so, the bulbs will be neither so firm nor so well shaped as those from seed of two, three, or more years' saving. The tops, in the former case, will be large, and consequently monopolise for themselves much of the material which ought naturally to have gone to the bulb; in the latter case the tops will be small, the bulbs large and well formed;—indeed, the proper preponderance will be, in this case, maintained between bulb and leaves. Cauliflower coming prematurely into flower—or what is technically called buttoning, because the abortive flower produced is not much larger than a good-sized button, and seldom worth half as much—may be offered as another example. Many other cases might be given; these, however, may suffice.

Returning, however, to how an expert gardener manages with less seed, in proportion to his wants, than one of less

experience, and in a more humble way of business: the former has a gradual succession to maintain, which scarcely admits of separate sowings to supply the niceness of his calculations; he therefore trusts to the three gradations, in which his seed-bed seldom disappoints him. He acts accordingly, and instead of taking the largest and strongest plants *only*, he takes part of all the three, and thus fills a much greater space of ground than he who calculates only on one crop, and contents himself with the first and strongest plants his bed produces, and, regardless of the others, digs them down, and trusts to another sowing, perhaps a month or more hence; which sowing, by the way, may suit his looser way of doing business. The gardener who has the superintendence of first-rate gardens is supposed to have a much greater knowledge of the principles of his profession—at least he should have so—than one whose field of operations is limited to a quarter of an acre, and who is often from circumstances ignorant of the rudimentary principles upon which he should act. These and amateurs are the class to which the sin of extravagance and too thick sowing is chargeable, and they in general consume far more seed, from misapplication, than is necessary. Fearful at sowing, either from want of confidence in the seed itself, or from being ignorant of the mode of proving its quality previous to sowing, they console themselves in either case with the certainty of being safe, and therefore sow unreasonably thick. There are, no doubt, on the other hand, some who, from penuriousness, err in sowing too thin, and not taking into calculation the losses by insects, frosts, and the doubtful quality of the seed, which such a class is of all the most likely to experience, having purchased *cheap*; and, in consequence, they find that their crop is a total failure. There is, however, no doubt that thin-sowing is preferable to thick-sowing, so far as the plant is concerned; and if seeds are to be depended upon, and were they of sufficient value to make it a measure of economy to plant them singly, instead of sowing them in the usual manner, there is no doubt, barring accidents, that the former mode would be preferable to the latter, and therefore one quarter of the seed usually ordered would suffice.

§ 4.—ROTATION OF CROPS.

The necessity of a rotation of crops—that is, not sowing or planting the same ground with the same species of seed or plants from which it has been cleared, but introducing a succeeding crop of as dissimilar a kind as possible—is founded upon two facts, namely, the excrementitious of the plants, and the exhausting of the soil by them. Brugmanns supposed he had discovered that some plants exude an acid fluid from their spongioles, which may be regarded as a peculiar kind of excretion, which becomes obnoxious to roots of the same kind, but not so to those of another species; and Macaire asserts that this property is almost general throughout the vegetable kingdom. De Candolle was of this opinion, and conjectured that the soil was not only rendered unfit for the growth of the same species in consequence of these excretions, but believed that, acting as a manure, they improved the soil for other species. This, coupled with the supposition that plants cannot digest their own excretions, seemingly explains to us why the soil becomes deteriorated by one kind of plant having long grown in it, and its unfitness to support a crop of the same kind until the fecal matter in it shall have become decomposed. Daubeny and Gyde deny this, and say that these excretions are not injurious.

Gyde's opinion was, that though plants have no power of selection, "but take into their texture any solution offered to their roots, they have little or no power of again excreting it; that any excretions are only of the true sap; and that plants watered with excretions receive no injury by it." This opinion has occupied, to some extent, the attention of physiologists within these two or three years, but, as it appears, as yet without any conclusive result having been arrived at.

In connection with this, Dr Lindley remarks ("Theory of Horticulture," p. 21), "In addition to their feeding properties, roots are the organs by which plants rid themselves of the secreted matter, which is either superfluous or deleterious to them. If you place a plant of succory in water, it will be found that the roots will, by degrees, render the water bitter, as if opium had been mixed with it; a

spurge (*Euphorbia*) will render it acid, and a leguminous plant mucilaginous; and if you poison one half of the roots of any plant, the other half will throw the poison off again from the system. Hence it follows, that if roots are so circumstanced that they cannot constantly advance into fresh soil, they will, by degrees, be surrounded by their own excrementitious secretions. It would also seem to follow that, under the circumstances just named, they would be poisoned, because they have little power of refusing to take up whatever matter is presented to them in a fitting state. But it is by no means certain that the excrementitious matter of all plants is poisonous either to themselves or to others; and therefore the consequences of roots growing in soil from which they cannot advance are uncertain, and only to be judged of by actual inquiry into the nature of the secretions." On the power of selection of food, the same high authority observes (p. 18), "Powerful as the absorbing action of roots is found to be, those organs have little or no power of selecting their food; but they appear in most cases to take up whatever is presented to them in a sufficiently attenuated form. Their feeding properties depend upon the mere hygrometrical force of their tissue, set in action in a peculiar manner by the vital principle. This force must be supposed to depend upon the action of the capillary tubes, of which every part of a vegetable membrane must of necessity consist, although they are in all cases invisible to the eye, even when aided by the most powerful microscopes. Whatever matter is presented to such a set of tubes will, we must suppose, be attracted through them, provided its molecules are sufficiently minute; and as we have no reason to believe that there is, in general, any difference in the size of the molecules of either gaseous matter, or fluids consisting principally of water, it will follow that one form of such matters will be absorbed by the roots of plants as readily as another. For this reason plants are peculiarly liable to injury from the presence of deleterious matter in the earth; and it is probable that, in many cases they reject it, it is because it does not acquire a sufficient state of tenuity, as in the case of certain coloured infusions.

This, although apparently a general rule, is not without its exceptions. If a pea and a grain of wheat are planted in the same soil, and placed in the same circumstances, it will be found that the latter will absorb silex from the soil, the former none; and this shows pretty clearly the power of selection. Dr Daubeny has shown that certain plants will not absorb strontian; and Saussure that the spiral-rooted polygonum, while it took up common salt (muriate of soda) freely, refused to absorb a solution of acetate of lime. "It is a curious fact," Dr Lindley remarks, "that the poisonous substances which are fatal to man are equally so to plants, and in nearly the same way; so that by presenting opium or arsenic, or any metallic or alkaline poison, to its roots, a tree may be destroyed as readily as a human being."

Cropping the same ground year after year with the same species of plant, or replanting a forest with the same species of trees, or indeed planting a young fruit-tree in the same situation and soil from which another had been removed, is attended with failure, for, in addition to the cause assigned above, the soil becomes exhausted of those parts it originally contained and has given out for the support of the previous crop, though it may still retain material of a different character, sufficient to enter into the constitution of a crop of a dissimilar kind. "As the inorganic materials which enter into the composition of plants vary much in their nature and relative proportions, it is evident that a soil may contain those necessary for the growth of certain species, while it may be deficient in those required by others. It is on this principle," says Professor Balfour, "that the rotation of crops proceeds—those plants succeeding each other in rotation which require different inorganic compounds for their growth. In ordinary cases, except in the case of very fertile virgin soil, a crop, by being constantly grown in successive years in the same field, will deteriorate in a marked degree. Dr Daubeny has put this to the test of experiment, by causing plants to grow on the same and on different plots in successive years, and noting the results:—

		Average of 5 years.
Potatoes,	{ in the same plot,	72.9 lb. tubers.
	{ in different plots,	92.8 " "
Flax,	{ same, . . .	15.0 " "
	{ different, . . .	19.9 " "
Beans,	{ same, . . .	32.8 " "
	{ different, . . .	34.8 " "
Barley,	{ same, . . .	30.0 " "
	{ different, . . .	46.5 " "
Turnips,	{ same, . . .	104.0 " "
	{ different, . . .	173.0 " "
Oats,	{ same, . . .	28.0 " "
	{ different, . . .	32.4 " "

"This shows a manifest advantage in shifting crops, varying from 1 to 75 per cent, the deficiency of inorganic matter being the chief cause of difference."—

Manual of Botany.

"The prevailing opinion," Loudon remarks, "has long been that plants exhaust the soil generally of vegetable food, particularly of that kind of food which is peculiar to the crops growing on it for the time being. For example, both potatoes and onions exhaust the soil generally; while the potato deprives it of something that is necessary to insure the reproduction of a good crop of potatoes, and the onion of something which is necessary for the reproduction of a large crop of onions. According to the theory of De Candolle, both crops exhaust the soil generally, and both render it unfit for the particular kind of crop; but this injury, according to his hypothesis, is not effected by depriving the soil of the particular kind of nutriment necessary for the particular kind of species, but by excreting into it substances peculiar to the species with which it has been cropped; which substances render it unfit for having these crops repeated."—*Sub. Hort.*, p. 436. Both these theories have been disputed, and this by practical reasoners, who naturally enough ask, How do they apply to plants long confined to the same soil—an orange tree, for example—which has luxuriated, without being either poisoned or starved, within the limits of a three-foot square box for a score of years? and how do perennial plants exist in the same soil for as great a length of time? The advocates of the one theory say the annual dropping and decay of the foliage supply at once general and particular nourishment. This does not, we suspect, apply to the orange tree we have taken as an example, because the leaves, if they even fell on the surface of the soil in the

box, would be daily removed. The others say the same droppings of the leaves, by the general nourishment which they supply, neutralise the particular excretions. Liebig advocated the exhausting principle, and showed, chemically, that the roots of trees and plants in time exhaust those principles contained in the soil which are most conducive to their respective wants. This appears to be both a conclusive and simple way of settling the question. He afterwards modified these views, and remarks, p. 33, edit. 1843, "Transformations of existing compounds are constantly taking place during the whole life of a plant, in consequence of which, and as the results of these transformations, there are produced gaseous matters which are excreted by the leaves and blossoms, solid excrements deposited in the bark, and fluid soluble substances which are eliminated by the roots. Such excretions are most abundant immediately before the formation and during the continuance of the blossoms; they diminish after the development of the fruit. Substances containing a large proportion of carbon are excreted by the roots and absorbed by the soil. Through the expulsion of these matters, unfitted for nutrition, the soil receives again, with usury, the carbon which it had at first yielded to the young plants as food, in the form of carbonic acid. The soluble matter thus acquired by the soil is still capable of decay and putrefaction, and, by undergoing these processes, furnishes renewed sources of nutrition to another generation of plants, and becomes humus."

We have many instances in practice, where the same crop has been grown on the same soil for many successive years, *vide* article ONION; and many others of a like kind could be adduced. Mr Stephens, in his excellent "Book of the Farm," vol. ii. p. 455, reasons on this subject practically, and we think judiciously. He says, "Experience has demonstrated that one crop after another of the same kind greatly reduces the fertility of all classes of soils. This conclusion might be drawn from reason as well as experience, since it is reasonable to suppose that crops of the same kind take the same sort of food out of the same kind of soil. Experience has also demonstrated that one crop after another, of a

different kind, does not materially reduce the condition of soils. This deduction, then, seems fair, that the condition of the soil is best maintained by taking different crops after one another; and as every crop, though of different kind, and deriving support from the soil, assists in exhausting it, a limit must be put to the number of crops that should follow one another. Though all crops derive food from the soil, one kind appropriates food in a different degree from another; and even the same crop takes food in different quantities, according to the state its product is allowed to proceed." Plants which ripen their seed, as cabbages, turnips, &c., when the ostensible object is to produce seed, draw more strongly on the soil than those which are grown for their leaves and bulbs only, as spinach and beet, &c. Hence the practice, in gardens, of uselessly allowing plants to shoot up into flower, much less seed, in spring, cannot be too severely reprobated.

The excrementitious theory is ingenious, if not even correct, and has occupied the attention of the chemist for many years. At the request of De Candolle, M. Macaire of Geneva instituted a series of experiments, which led him to conclude that, in the formation of the seed, or other nutritious parts of plants, the sap is digested; that it takes up certain elements, and deposits others, which are the residue of the process; and these, being no longer necessary for the formation of the seed, are rejected by the vital action of the plant, and exude by the roots. "Our ignorance of the functions of vegetable life prevents us from seeing the effects produced on the sap by the expansion of the blossoms, or the ripening of the seed; but experience leads us to perceive that certain plants thrive best after certain others, and that in this case they are always of distinct and different natures, and of different natural botanical families. Macaire and other scientific men observed the change that took place in the water in which wheat had been made to grow. They found a deposit in the water of the nature of bitter extract, and this they concluded to be excrementitious. Beans grew well in this water; and, on the other hand, wheat thrived in the water in which beans had grown."—*Donaldson on Soils and Manures*, p. 30. The effects of fal-

lowing land, or deep-digging, ridging, and trenching, are said to be the sweetening the soil, because the excrementitious matter becomes washed out by the rains, decomposed by the action of light and air, or buried beyond the reach of the roots, and may remain so until decomposed or completely changed by some unseen and as yet imperfectly understood cause.

The alternation of crops becomes also necessary, as a safeguard against the attacks of insect enemies. Thus, some of the insects which are most injurious to the Brassica tribe, for example, by depositing their eggs in the soil, when the period of their own brief existence terminates, secure by this means a numerous progeny to commit their baneful depredations on the succeeding crop; whereas, if a different kind of plant were substituted, it is, in many cases, certain that they would die of starvation, rather than feed on food of a character different from that destined for them by nature. Take, for example, a plant of their own natural order, the black mustard, (*Sinapis nigra*), which has been recommended to be sown on ground infected with the larvæ of insects feeding on the cabbage tribe: the roots of the mustard being too acrid for them, they have actually died of starvation.

As a restorative or compensation to the soil for a continued cropping with the same species of crops, certain materials, forming in themselves the inorganic constituents of plants, have been recommended. Indeed, chemically speaking, one piece of ground may possibly be made to produce the same species of crop *ad infinitum*. To carry out, however, these ideas, it will be necessary to ascertain the matter abstracted from the soil by such crops, and then to add to them, at each sowing or planting, an equivalent, *and something more*, of the ingredients of the same nature as that of which the ground has been robbed by the preceding crop. This is, however, only meeting the subject midway, if even so much.

To ascertain correctly what is the food of plants, we must first ascertain what they themselves are composed of; for whatever elements constitute their structure, these elements are their true food: therefore it is the plant more than the soil whose component parts should be

determined. Chemists have laboured for years in determining the qualities of soils and manures, while they have by far too much neglected the analysis of the plants themselves, which is the first and most important consideration.

It is a pretty generally received opinion amongst many cultivators that each species of plant requires a distinct species of food to be presented to it from the soil; but vegetable physiologists have shown that the organs of one plant derive their food from substances which concur in the true nutrition of plants generally; or, that is to say, plants of the most opposite characters and properties, as articles of food or vehicles of poison, will not only exist, but flourish in the same flower-pot of earth or of manure—a circumstance opposed to the theory that each species requires a different element of food.

M. Boussingault favoured the opinion that there was no absolute necessity for a rotation of crops “when dung and labour can be readily procured. Nevertheless,” he says, “there are certain plants which cannot be reproduced upon the same soil advantageously, except at intervals more or less remote. The cause of this exigence on the part of certain plants is still obscure, and the hypotheses propounded for clearing it up are far from satisfactory. One of the marked advantages of alternate culture is the periodic cultivation of plants which improve the soil. In this way a sort of compensation is made for exhaustion. The main thing to be secured, in the rotation of crops, is such a system as shall enable the husbandman to attain the greatest amount of vegetable production with the least manure, and in the shortest possible time. This system can alone be realised by employing, in the course of rotation, those plants which draw largely from the atmosphere. The best plan of rotation in theory is that in which the quantity of organic matter obtained most exceeds the quantity of organic matter introduced into the soil in the shape of manure. This does not hold in practice. It is less the surplus amount of organic matter over that contained in the manure, than the value of the same matter, which concerns the cultivator. The excess required, and the form in which it should

be produced, must vary widely according to locality, commercial demand, and the habits of the people, considered wholly apart from theoretical provisions. One point in theory which should agree with practice is this, that in no case is it possible to expect more organic matter, and particularly more azotised organic matter, than the excess of the same matter contained in the manure which is consumed in course of the rotation. By acting upon another presumption, the productiveness of the soil would be infallibly lessened. Hence it may be inferred how closely the study of rotations is connected with that of the exhaustion of the soil."

Such is a brief epitome of the two leading theories—hypotheses, perhaps, more properly they should be called. The practical deductions to be drawn from them differ little, and add as little to what observing cultivators have long been taught by experience—namely, that crops, the plants of which have a close affinity to each other, belong to the same natural order, or resemble each other in structure or habit, should not follow each other in cultivation. Cruciferous plants—that is, the cabbage, kale, or turnip tribe—should be followed by those of the leguminous order, or the pea and bean tribe, and *vice versa*. Deep-rooting plants, like the beet, carrot, parsnip, &c., should be followed by such as spinach, lettuce, &c., and *vice versa*. Again, plants which have been grown for their fruit, such as seed-cabbage, and even pease, beans, scarlet runners, although the three latter do not remain to ripen their seeds, take more from the soil than cabbage, celery, or spinach, which are grown for their leaves alone. Perennial plants, such as sea-kale, asparagus, globe artichoke, &c., should never succeed each other, but should be succeeded by onions, leeks, or other annual crops of short duration, of essentially different characters. Indeed, no two exhausting crops should succeed each other, but rather the least exhausting, such as lettuce, endive, &c., should be succeeded by cabbage or the like.

The following excellent article on rotation cropping appeared in "The Gardeners' Chronicle," and deserves the special attention of every cultivator, whether the field of his operations be

large or small. "Rotation crops consist of those most required for culinary purposes, such as pease, beans, French beans, broccoli, cabbage, turnip, carrots, parsnip, beet, onions, savoys, spinach (winter), and winter greens, celery, cauliflower, leeks. Pease and beans should be sown from February to June." In Scotland we sow on till the beginning of August, as our moist mild climate is more favourable for producing crops during September, October, November, and we have had them occasionally up to nearly Christmas, seasons when pease have hitherto been almost unknown in the neighbourhood of London, where the drought and heat prevent their natural development. The London Horticultural Society have this season taken up this matter, and we believe that, by counteracting the effects of heat and drought, both of which are pretty much under the control of the cultivator, green pease will soon be seen in Covent Garden market on Lord Mayor's Day, as they are now on the 1st of June. "The first crop of pease will be clear for early broccoli in the end of June, and for the other seasons until September, for later broccoli, savoys, borecole, Brussels sprouts, collards or coleworts, and spring cabbage. This crop should have a slight crop of manure. Broccoli ground will be cleared of early sorts by winter"—in Scotland, say the end of November—"and should be ridged up all winter for a crop of carrots, which should be sown as early as possible. The later broccoli, colewort, sprouts, &c., will make way by April or the beginning of May for beet, parsnip, scorzonera, and salsify. Carrots, beet, and parsnips will be clear in the beginning of November, when the ground must be again ridged up for winter, and have a good coat of dung ready for cauliflowers, onions, garlic, and shallots, the two latter being planted in November, and also the principal crop of turnips sown in the end of March and April. Cauliflower, onions, and turnips will be clear from July to September; the cauliflower, shallots, &c., in July, for autumn spinach and endive; the onions for winter spinach, and the turnips for spring onions, winter lettuce, and other secondary crops. Spinach, endive, and spring onions will be clear by the end of May for savoys, winter

greens, red cabbage, cauliflower, and leeks, all of which require a moderate coat of manure. Savoys, winter greens, red cabbage, &c., will be ready for early potatoes in April and May. Potatoes will make way in July and August for turnips, spring cabbage, late broccoli, and such crops, if wanted. Turnips, cabbage, and broccoli may be cleared in May for celery and cardoon trenches, if all the ground is wanted; but if not, the cabbage may be allowed to remain for sprouts during all the summer. The intermediate spaces between the trenches may be planted with lettuce or any other secondary crops: dung must be given for celery, of course. Celery and similar crops will, in part, make way in autumn, when the ground should be ridged up for the winter, and the remainder as soon as the entire crop is clear; the ground will then be ready for French beans, scarlet runners, cauliflower, cucumber, and tomatoes, in the end of April or beginning of May. French beans will be clear by November, when the ground should be again ridged up all winter, to be ready for pease and beans as at first begun. This will make eight or ten years between the return of the principal crops to the same place, and, by judicious management of the secondary division" (such as salads and short-lived crops) "among the rotation crops, every space of ground between one crop and the other may be occupied to advantage during the intervals of cropping."

The following shows the order of rotation:—1, pease and beans; 2, broccoli, savoys, winter greens, collards—*i. e.*, spring cabbage; 3, carrots, parsnips, beet, scorzonera, salsify, "skirrets, Hamburg parsley;" 4, onions, cauliflower, turnips; 5, spinach, spring onions, and other secondary crops; 6, savoy, broccoli, winter greens, red cabbage, leeks; 7, potatoes; 8, turnip, cabbage, broccoli; 9, celery, cardoons; 10, French beans, &c.

"Secondary crops are those of the shortest duration, such as lettuces, radishes, small salads, annual herbs, and very early pease and beans, (sown in November,) very early cauliflowers, very early turnips, and early potatoes, all of which will require a warm south border."

This is a specimen of the rotation practised by the best cultivators around Lon-

don, and, taking the difference of latitude into consideration, it is calculated for a great part of Scotland and Ireland. It will be remarked that this system of rotation comprises only the annual or biennial crops, and therefore we propose it as the precursor course to the *systematic arrangement of the contents of the kitchen-garden* sketched out, (*vide p. 7.*) and we know of no better rotation that can be followed. This rotation embraces eight years, but, by following ours as an addition course, the change may be extended to the eleventh or twelfth year. The author of the above rotation is one of the best cultivators around London, and calculates, of course, that each crop is to be removed as soon after it is fit for immediate use as the consumption calls for, and hence the rapidity of his movements. The private gardener can do the same thing by keeping up a very close succession (as elsewhere noticed); but, unfortunately, in many private gardens, from causes the cultivator has no control over, crops are allowed to come to too full a state of maturity before they are commenced upon, and kept lingering on the ground long after they should be consigned to the rot heap, or, much better, trenched into the ground, restoring to it much of those elements they had abstracted from it.

According to Mr Prideaux, in "The Gardeners' Chronicle," 1848, quoted by Mr Stephens in "The Book of the Farm," vol. ii. p. 453, the following quantities of mineral ingredients are removed from an acre of soil by a single crop of beans. "Beans, of a crop of 25 bushels of grain and 2800 lb. = 1 ton 5 cwt. of straw, carry off from an acre of soil these quantities:—

	By the grain.	By the straw.	Total.
	lb.	lb.	lb.
Potash, .	13.60	90.21	103.81
Soda, .	4.30	2.72	7.02
Magnesia, .	3.15	11.38	14.53
Phosphoric acid, .	15.20	12.32	27.52
Sulphuric acid, .	0.40	1.85	2.25
Chlorine, .	0.30	4.35	4.65

36.95 122.83 159.78

—or gross weight to be returned to the acre."

If the soil is to be maintained in possession of all its natural mineral ingredients, it follows, after such abstractions as this,

that means must be employed for their restoration. This is to be effected by what are usually called mineral manures, or by the aid of such vegetable ones as may contain them all or in part.

Should, however, the recent discovery made by M. Barral, a French chemist of great respectability, prove to be correct—and of that there appears to be little doubt—these ingredients, annually abstracted from the soil, are given back or provided again in a way and to an extent hitherto unsuspected. Chemists long ago had determined that the air we breathe consisted only of two distinct gases, oxygen and nitrogen, with a minute proportion of carbonic acid dispersed through a variable quantity of aqueous vapour. To these Liebig added carbonate of ammonia as constituting the essential parts of the whole, considering the minute traces of lime, potash, and common salt, as too insignificant to deserve notice. This celebrated chemist still further held as quite secondary and insignificant the presence of nitric acid, the action of which is so important in conveying nitrogen to the vegetable system, and declared the quantity as being too small to be even estimated in the rain of thunder-storms. M. Barral has, however, shown this in a different light. The following explanation of his experiments, with remarks by the editor, appears in a very recent number of “The Gardeners’ Chronicle,” 1853: “This eminent chemist was led, during the last six months of 1851, to examine minutely the water collected in the rain-gauges of the Observatory at Paris. His mode of investigation is declared by Messrs Dumas, Boussingault, Gasparin, Regnault, and Arago, names foremost in French science, to be free from all objection, and to bear the most severe counter-trials to which they could expose it. M. Barral states, that although the quantities of the following substances varied in different months, yet the monthly average, from July to December inclusive, was as follows:—

Substances in a cubic metre of Rain Water.

Nitrogen,	8.36 grammes	—	129.	grains.
Nitric acid,	19.09	—	294.	”
Ammonia,	3.61	—	55.7	”
Chlorine,	2.27	—	35.	”
Lime,	6.48	—	100.	”
Magnesia,	2.12	—	32.7	”

“He did not ascertain whether all these substances are contained in rain-water collected at a distance from towns. But Mr Bence Jones found at least nitric acid in rain-water collected in London; at Kingston, Surrey; at Melbury, Dorsetshire; and, far from any town, at Clonakelly, in Ireland. If we assume that M. Barral’s averages represent what occurs on an English acre, the quantity of such substances deposited on that extent of ground may be safely estimated as follows. The average depth of rain which falls in the neighbourhood of London is well ascertained to be about 24 inches per annum. This is at the rate of 87.120 cubic feet, or 2466 cubic metres of rain-water per acre; and this, according to the proportions per cubic metre in the preceding table, would afford annually of—

Nitrogen,	45½ lb.
Nitric acid,	103 ”
Ammonia,	19½ ”
Chlorine,	12½ ”
Lime,	35 ”
Magnesia,	11 ”
Annual total per acre of these ingredients returned to the soil by the agency of rain alone,		227 ”

“Of these substances, the three first are of the utmost importance, on account of their entering so largely into the indispensable constitution of the food by which vegetable life is sustained. The quantity of ammonia thus ascertained to exist is about what is expected in 2 cwt. of Peruvian guano; and bountiful nature gives us, moreover, nearly 150 lb. of nitrogenous matter, also suited to the nutrition of our crops. Nature gives us food, and we improvidently waste it. What with shallow cultivation on the one hand, hard ill-tilled land, puddled furrow-trenches, and polished furrow-slices, rain-water, thus highly charged with the most nutritious ingredients, either runs off to ditches, or is so ill directed that it very imperfectly reaches the roots. On the other hand, by means of close cropping, that which is intended to bathe every part of a plant, and to be instantly absorbed by its verdant surface, is as completely turned aside as if two-thirds of the crop grew beneath a penthouse.”

From this it will be seen that nature is

constantly restoring to the soil a vast amount of those ingredients taken up by the crops, without the aid of man; but, that these valuable supplies be not wasted, it behoves man to keep the soil in a proper state to receive them. This can only be done by what we have so strongly urged elsewhere—deep cultivation and thin cropping—two important essentials in culture sadly neglected in most gardens, trenching for almost every crop being a thing scarcely thought of, notwithstanding we are well assured that very much of the success of the London market-gardener, in producing such enormous crops, depends on this operation alone. Were half the amount of the value of the manure which is yearly crammed into garden soils expended on trenching, and keeping the surface afterwards open, the advantages would be soon made apparent; and without that, all the manure, whether special or common, whether mineral or vegetable, and however applied, may be regarded as so much capital thrown away.

Again, besides the amount of matter restored to the soil, as shown above by M. Barral, an additional supply is returned by the plants themselves, whose leaves are constantly decomposing carbonic acid, which they absorb from the atmosphere, liberating the oxygen, and appropriating the carbon to their own use; they derive supplies of nitrogen for the formation of their albuminous constituents from the volatile carbonate and nitrate of ammonia, and these they restore to the soil when they are buried in it. From the earliest ages certain crops have been grown for the express purpose of being returned to the soil for its enrichment, a practice probably of more ancient date than that of alchemy, and 3000 years earlier than modern chemistry. The exhaustion of the soil by crops is not so very alarmingly great, under good management, as some would have us to believe, and would be much less so if those parts of vegetables that are not to be directly consumed by man were returned to it at the time. Out of a crop of cauliflower, not one-fourth of the bulk of the crop is useable; hence, if the other three-fourths were immediately dug into the ground on which they were produced, they would return to it very nearly as much as they

had taken from it during their growth, if not more. It is bad management that exhausts a soil; and one of the worst parts of bad management is taking the whole vegetable produce off the ground, and either not returning it at all, or doing so after it has become so much decomposed and exposed to atmospheric action as to have nearly lost all its fertilising properties. In gardens much of this is daily carried on, too many believing that plants derive all their food from the soil. But such is not the case; the greater part of vegetation is derived from atmospheric sources, and when that is returned to the soil by digging it in, it in this way supplies it with more of the organic elements essential to future vegetable growth than the soil contained before the crop was sown or planted; in other words, it is enriched by the carbon, hydrogen, and nitrogen which the vegetable had obtained from sources entirely independent of the soil.

Plants have the power of converting the materials which constitute both common and special manures by a species of elaboration going on within them, so as to fit and appropriate the necessary quantity of each, and to dispose of them throughout the various parts of their structure, leaves, stems, seed, roots, &c.; and not only that, but they are capable of supplying themselves at different times, and even in different parts of the same plant, according to their respective natures. "They all form," says Professor Johnston (in "Experimental Agriculture," p. 9), "more or less constantly and abundantly, a portion of the fixed and solid matter of the plant taken as a whole. They may not be found in any one part of the plant, when separated carefully from the rest, but, in the solid parts of the plant, taken as a whole, they are all, and always to be met with. When thus deposited, they become for the most part dormant, as it were, and for the time cease to perform active chemical functions in the general growth, though, as vessels or cells, they may still perform a mechanical function. They undergo various chemical changes in the intercourse, chiefly while circulating or contained in the sap, by which changes they are prepared and fitted for entering, when and where it is necessary, into the solid

or fixed parts of plants. Thus the starch of the seed is changed into the soluble dextrin and sugar of the sap of the young plant, and then again into the insoluble cellular fibre of the stem or wood as the plant grows; and, finally, into the insoluble starch of the grain, as its seed fills and ripens. They each exercise a chemical action more or less distinct, decided, and intelligible, upon the other elementary bodies, and the compounds of them which they meet with in the sap of the plant. In regard to some substances, such as potash and soda, the sulphuric and phosphoric acids, this last function appears to be especially important. These substances influence all the chemical changes which go on in the interior of the plant, and which modify and cause its growth. The same is true of the nitrogen which the plant contains. This elementary body, in the form of albumen or some other of the numerous protein compounds which occur in the sap, presides over, or takes part in, almost every important transformation which the organic matter of the living plant undergoes. Thus it is always abundantly present where the starch of the seed or of the tuber is dissolved, and sent up to feed the young shoots; and again, when the soluble substances of the sap are converted into the starch of the grain of the tuber, or of the body or pith of the tree, one or other of the protein combinations is always found to be present on the spot where the chemical change in the transformation is going on. Besides these general functions, the several substances found in plants exercise also special functions in reference to vegetable life and growth. Thus—

“*Nitrogen* is most abundant in the sap of young plants, takes part in most of the changes of organic compounds which go on in the sap, and fixes itself, as the plant approaches maturity, in greatest abundance in the seeds and in the green leaves.

“*Potash and soda* circulate in the sap, influence chemical changes very much, and reside or fix themselves most abundantly in green and fleshy leaves, and in bulbous roots.

“*Sulphuric acid* is very influential in all chemical changes; is found, in most cases, in those parts of the plants in which

potash and soda abound, and deposits a portion of its sulphur wherever the compounds of nitrogen form a notable part of the substance of the plant.

“*Phosphoric acid* exercises also much influence over the chemical changes of the sap, and finally fixes itself in greatest abundance in the seeds and other reproductive parts of the plant.

“*Lime* is very important to healthy vegetable growth, as practical experience has long testified. Among other duties, it appears to accompany the phosphoric acid in the sap of plants, and to deposit itself, in combination with organic acids, in the leaves and bark, and with phosphoric acid in some seeds and roots.

“*Magnesia* appears also to attach itself very much to phosphoric acid in the sap, and fixes itself, in combination with the acid, principally in the seed.

“*Chlorine*.—The chemical functions of this substance in the sap are less understood even than that of the other substances above mentioned. It exists chiefly in combination with soda, and is much more abundantly present in some plants, and in some parts of plants, than in others. Though, as I have said, its immediate chemical functions in the plant are not understood, it forms a most important constituent of the plant, in so far as the after uses of vegetables as ‘articles of food’ are concerned.

“*Silica* exists in the sap in a soluble form, and deposits itself chiefly in the exterior portions of the stems and leaves of plants. It is supposed there to serve as a defence to the plant against external injury, and to give strength to the stem, in the case of the grasses and corn-yielding plants; but what chemical functions it performs, if any, in directly promoting vegetable growth, we can scarcely as yet even venture to guess.”

However extraordinary it may appear to the young cultivator, (and we know many of riper years who scout the idea that plants take up and are in part constituted of FLINT,) yet such is the case; and, moreover, all plants contain mineral matters, such as iron, copper, flint, sulphur, &c.: if we may venture to hazard a supposition, their presence even in the leaves of the most delicate grass is necessary in the formation of what may be called the bone of the plant; and no

doubt they answer a purpose analogous to the bones in animals, formed of lime, which is a mineral substance also.

Although, however, the presence of mineral substances in plants is necessary, yet they do not in general abound in large quantities. Their presence is not the result of accident, but of wise design, as beautifully shown by Professor Lindley in "Theory of Horticulture," p. 356—"For although it may be asserted that the presence of iron, copper, or other substances, in plants, in minute quantities, is accidental and unimportant, yet such a supposition is gratuitous, if not altogether unfounded; for I do not know what warrant we have for saying that any of the constant phenomena of nature, however minute they may seem to be, are accidental. This at least is certain, that where mineral substances occur abundantly in plants, they are part and parcel of their nature, just as much as iron and phosphate of lime are of our own bodies; and we must no more suppose that grasses can dispense with silica in their food, or marine plants with common salt, than that we ourselves could dispense with vegetable and animal food.

"Flint is found on the exterior of the whole graminaceous order without exception. It forms the polished surface of the cane palm, the grittiness of many kinds of timber. Sulphur abounds in cruciferous plants, especially mustard; copper in coffee, wheat, and many other plants, (it is believed in the state of phosphate;) iron as a peroxide in tobacco, &c." In the fruit of the strawberry it has been found; and the medicinal properties of that fruit are accounted for by many physicians by its presence. De Candolle, in "Physiologie Végétale," p. 389, asserts that 3650 kilogrammes of copper are consumed annually in France in the article of bread; and M. Sarzeau says that 560 kilogrammes of the same mineral are swallowed annually in France in the article coffee alone.

How these mineral substances are taken up by vegetables is no less curious than their presence in them. Most chemists believe they are in some way or other taken up by the roots. The experiments of John upon this matter, as quoted by Dr Lindley ("Theory of Horticulture," p. 357), would lead us to believe that

they are supplied from the atmosphere as well; for John "found that the *Ramalina fraxinea* and *Borrera ciliaris*, two lichens, contained a large quantity of the last metal, although he could not find a trace of it in the fir-tree, on the topmost branches of which the lichens grew. We cannot, therefore, suppose that such things are the result of accident, and that it is unimportant to the plants containing minerals thus constantly, whether such substances are present in their soil or not." We are afraid that some of our agricultural chemists have jumped at conclusions hurriedly, and drawn deductions which will not bear the test of close investigation. When they give us to understand, that because a crop of wheat, for example, abstracts 76.22 lb. of mineral substances from the soil per acre, per annum, consisting of potash, soda, magnesia, phosphoric acid, sulphuric acid, and chlorine, that the same weight (viz. 76.22 lb.) of these ingredients, contained in special manures, is the exact and proper return to be made for that abstracted by the crop, so as to leave the soil in the condition in which it was previous to the seed of the crops being sown.

Such calculations as these appear to have been made without duly considering atmospheric effects, because it appears there has been no allowance made for them. "Plants feed more by their leaves than by their roots."—LINDLEY. "It is commonly supposed that plants derive the whole of their food from the soil, but this is a great error. It is a fact well ascertained by chemical experiments, that plants derive the greater part of their nourishment from the air, although the soil is equally essential to their growth."—SOLLY, in *Rural Chemistry*, p. 96. "Plants possibly draw from the atmosphere more than agriculturists commonly suppose; and the soil furnishes, independently of saline and earthy substances, a proportion of organic matter larger than certain physiologists admit."—BOUSSINGAULT. "The leaves spread out their broad surfaces into the air for the same purpose, precisely, as that for which the roots diffuse their fibres through the soil; the only difference being, that, while the roots suck in chiefly liquid, the leaves inhale almost wholly gaseous food. In the daytime, whether in the sunshine or in the shade, the green

leaves are constantly absorbing carbonic acid from the air, and giving off oxygen gas; that is to say, they are continually appropriating carbon from the air. When night comes this process is reversed, and they begin to absorb oxygen, and give off carbonic acid. But the latter process does not go on so rapidly as the former; so that, on the whole, plants when growing gain a large portion of carbon from the air. The actual quantity, however, varies with the season, with the climate, and with the kind of plant. The proportion of its carbon which has been derived from the air is greatly modified, also, by the quality of the soil in which the plant grows, and by the comparative abundance of liquid food which happens to be within reach of its roots. It has been ascertained, however, that in our climate, on an average, not less than from one-third to four-fifths of the entire quantity of carbon contained in the crops we reap from land of average fertility is really obtained from the air."—J. F. W. JOHNSTON, in *Agricultural Chemistry and Geology*, p. 40. And without quoting other authorities—of which there are many—we refer to the recent experiments made by M. Barral, given above, in which he shows that 227 lb. of the six elements of fertilisation are returned to the soil, per acre, per annum, by the rains which fall alone; while according to data, given above, by agricultural chemists, 76.22 lb. are all that is required per acre to re-establish the soil to its former condition, after a crop of wheat has been taken from it, so far as these mineral ingredients are concerned.

Nitrogen is required in great abundance in most plants, in some more than in others; and to obtain this from the atmosphere, the agency of saline substances may be necessary; for of such importance is their influence in this respect, that crops have been grown on soils destitute of organic matter, but containing saline substances, which procured sufficient nitrogen from the atmosphere to cause the plants to flower, fruit, and yield ripe seed, notwithstanding they were only supplied with distilled water, which, of course, could convey to the plants none of those fertilising elements discovered by M. Barral in rain-water. Mr Stephens, in summing up the evidence he has so carefully collected, concludes

by observing, in "Book of the Farm," vol. ii. p. 455—"Upon the whole subject of special manures, the rationale of their application may be based upon the certainty of the fact, that a large produce will be obtained, if we only return to the soil the mineral constituents of the crops we cultivate, in combination with nitrogenous substances, and the materials should be in a state to become fit for assimilation by plants." We are far from despising the use of special manures, but we would employ them as auxiliaries only, and advise the cultivator to consider as his sheet-anchor the contents of a well-managed dung-yard, which contain nitrogen in great abundance, which is known to excite the growth of vegetables, and also to render their products more valuable as food for man. It also contains much carbon, which, entering into their structure, imparts to them firmness of texture, and strength to maintain themselves in an upright position—the only position in which they could be placed, to derive the necessary advantages of atmospheric influence.

We look upon mineral or special manures, applied as restoratives in the routine of rotation, in the light of *make-shifts*; and whilst we admit their great value in agriculture, where, as things are managed, a sufficient quantity of stable-yard manure cannot or is not to be had—and also their importance in elevated situations, to which it would be too expensive to transport it—still we would not have cultivators to place their dependence on them alone. Besides, there is more than mere manurial applications required. The soil must be prepared for their reception, so that the process of free and copious evaporation may go on; and this cannot be expected to be completely realised, unless that soil be wrought to a considerable depth, and thoroughly amalgamated with those additions, whatever they may be, to insure a gaseous supply of food through the leaves, in addition to what is absorbed by the roots. Notwithstanding all this, and admitting that one species of crop may be grown for several continuous years on the same ground, it is, nevertheless (whether the cause rests in the exhaustion or excrementitious theory), wrong to crop the same ground, unless under peculiar cir-

cumstances, two successive years with the same species of crop.

Pulverising and trenching may be regarded as a species of rotation, because by them the surface of the soil may be transposed, or the whole mass thoroughly incorporated together; thus presenting to a great extent new food to plants, both for facilitating the necessary chemical changes, and the admission of rain and air—the latter so important to the roots of plants. Deeply pulverised soils are increased in temperature, as well as rendered more uniform in that respect. The air admitted carries with it, during summer, heat from the sun, which is daily accumulating, and retained for a length of time, the earth being a bad conductor of caloric. "The free admission of atmospheric air to soil is also necessary for the decomposition of humus, or organic matter, by which carbonic acid is formed; and atmospheric air is also a great source of nitrogen, which has been lately found in all plants, and more especially in the spongioles of the roots. —*Suburban Hort.* p. 35. "And hence," says LIEBIG, p. 190, "the great value of animal manures to plants, all of which contain nitrogen, but especially those of carnivorous animals."

From the comparative uncertainty, as regards a correct analysis of plants, in which chemists have left us, we cannot see, not knowing the exact amount of the ingredients of the soil which plants are supposed to carry off with them (both in their growing state, and more especially when they have arrived at their fullest maturity), what amount of those ingredients should be added to the soil, to make up for its supposed loss, or even what these are. Professor Johnston, in "Lectures on Agricultural Chemistry," &c., p. 528, admits "that we scarcely know as yet what any one entire plant, when fully ripe, carries off from the soil;" and in another part of these "Lectures," he says "that our knowledge of the inorganic constituents of plants is yet in its infancy, and that our present opinion upon the subject ought, therefore, to be permitted to hang very loosely about us."

It appears, in connection with the rotation of crops, as well as with the application of manures, that too much stress has

been laid upon vegetable chemistry, and by far too little regard paid to vegetable physiology; the connection between both is so intimate and important as to render them, in the pursuit of true conclusions, inseparable. "Intimately connected with vegetable chemistry," says Mr Edward Solly (in *Rural Chemistry*, p. 121), "is the study of vegetable physiology: a knowledge of the one is essential to the perfect comprehension of the other, for it is impossible well to understand the chemical changes going on in the organs of plants, if we are wholly ignorant of the forms and structures of these organs; and, on the other hand, the most complete knowledge of the anatomy of vegetables could never lead any one to sound and correct conclusions respecting the nutrition of plants. It is rather to be regretted that both chemists and physiologists have appeared to avoid availing themselves of the advantages which both might have derived, by studying the results which the others had obtained. It is only by comparing together the observations of both that correct conclusions can be formed." The researches of Grew, Malpighi, and Duhamel, did much in elucidating the structure of plants, and the modes by which they derived sustenance; indeed, they may be said to have laid the foundation of vegetable physiology. In more recent times, Decaisne, De Candolle, Mirbel, Dutrochet, and Brongniart, in France; Meyen, Mohl, Link, and Schleiden, in Germany; Amici in Italy; and Knight, Hooker, Henslow, Brown, Griffiths, and Lindley, in England, by careful observations, and the advantages of improved instruments, have reduced vegetable physiology from a series of vague and uncertain dogmas to a comparatively perfect system. Little had been done since the days of Priestley and Ingenhousz in the improvement of agricultural chemistry, save the labours of Sir Humphry Davy: these, however, an early death prevented him from prosecuting, for we dare scarcely say completing. It remained, therefore, for Liebig to do almost single-handed for vegetable chemistry what those we have named above, with many others, had been zealously engaged in doing for vegetable physiology. In his "Organic Chemistry," in tracing the sources by and from which plants derive their food, he has strongly

drawn attention to the importance of physiology combined with chemistry. "He has exposed the fallacy of many of the theories which had been formed to explain them, and has established" (as Mr Solly remarks) "on good evidence the simple chemical rules which regulate the growth of plants. Although much has been done, and although chemists have laboured to remove the perplexities which encompassed the subject, there is still a very great deal that requires investigation; many important points are as yet imperfectly, or even not at all, explained; and many questions must be satisfactorily settled before a complete system of agricultural chemistry can be established. Till these difficulties are removed, it is premature to expect that chemistry can be of more than partial assistance to agriculture; for whilst many of the fundamental laws of this section of chemistry are still scarcely understood, all attempts to apply them to practice must be incomplete and liable to error."

The rotation of crops in gardens is an important element in good management. They are, or ought to be, carried out upon two different systems—namely, the successional and simultaneous modes of cropping. The first has its chief feature in covering each piece of ground with only one species of crop at the same time, while simultaneous cropping is founded upon the practice of having several. The first presents the greatest appearance of order and system, and hence is that most generally followed in private gardens; while the latter, although less apparently systematic, is, to a certain extent, so in reality, and affords the largest return of produce, and is therefore often followed by commercial growers, who will, for example, sow with a crop of onions a thin crop of radish, lettuce, and sometimes a few carrots. The two former are removed early for use, leaving the onions to ripen off afterwards, and thus affording them more room as they increase in size. In the latter case, the carrots, sending down their roots to a greater depth, appropriate to themselves their own peculiar species of food, leaving the onions to extract theirs from nearer the surface; and, in some cases, carrots so grown are found to escape the grub. Simultaneous cropping is also carried on where the drill

system is followed; and hence a piece of ground may be thus stocked:—tall growing pease, Jerusalem artichokes, scarlet runners, &c., which attain a height of from 6 to 10 feet, may be planted at distances of 20 or 30 feet apart; garden beans, or low-growing pease, may be sown between these at a proper distance; and between these, cabbage, spinach, &c., may be planted or sown, thus affording to all a full share of light and air. Another advantage arising from simultaneous cropping is, that crops will be progressing in different stages of growth, so that, as the most advanced is cleared off, the next in order will supply its place; or, when one crop is removed, another of a dissimilar kind may be immediately planted.

Successional cropping is best calculated for poor soils, and for gardens where the supply of manure is limited, as well as where the garden is small. The other cannot be so well carried out, unless the soil is in the highest possible state of cultivation; and also in that order of things where the *whole* crop is removed almost at once, as in the case of sending it direct to the market; whereas in a smaller private garden it is only removed in small quantities at a time, according to the consumption, and therefore hangs longer upon the soil than is in accordance with this mode of cropping.

§ 5. TRANSPLANTING CULINARY ESCULENTS.

There are, for the most part, only three objects in transplanting these (some of which, however, do not admit of the operation at all), as the common turnip, whether for crop or seed; while the Swedish turnip, radish, parsnip, beet, scorzonera, salsify, skirret, &c., if not improved by the operation, suffer no injury by it if properly performed. Advantage is taken of this, and failures in portions of such crops are made up by thinning where they are too thick, and thus filling up deficiencies. In sowing for seed, transplanting has its advantages in this,—the roots can be selected, and misshapen ones rejected. All the Brassicæ—comprising the cabbage, sprouts, savoys, greens, cauliflower—are amazingly improved by transplanting from the seed-bed once or twice

before their final planting out. It increases the formation of extra roots, enables the cultivator often to detect the symptoms of club, as well as gives opportunity for the rejection of malformed plants. The pea and all the beans are improved in precocity. The process, however, would be unprofitable in the case of very large crops, and in the saving of seed. In the latter case, a removal of all weak and inferior varieties should be scrupulously attended to. Spinach does not admit, unless upon extraordinary occasions, transplantation; nor do the whole tribe of small salads, such as cress, mustard, &c. Lettuce admits of it freely, and so does endive: both may be grown to great advantage in small seed-beds, and when fit for removal placed to succeed crops which, while they (the latter) have been in a state of preparation, have been yielding their return. They, with celery, cardoons, &c., are grown from seed first, to forward them for transplanting, and to economise room. Onions admit of it with impunity, leeks with singular advantage, while carrots will not submit to the ordeal. Potatoes transplant freely, if the roots are preserved; and all the perennial crops, such as asparagus, sea-kale, &c., are benefited by the operation. "It is easy thus to see," Mr Loudon very justly observes (*Sub. Hort.* p. 621), "that by the transplanting system half the garden-ground will suffice that is requisite for the sowing system; and as a proof of the economy of this system generally, it may be observed that it is the one followed by all the market-gardeners in the neighbourhood of London. Another advantage attendant on the transplanting system—more especially in the case of esculents, the leaves of which are the parts used—is, that the plants, being deprived of part of their tap-root, throw out a greater number of lateral roots, in consequence of which the production of radical leaves is encouraged, and the tendency to run to flower is retarded; while a more succulent growth is induced, owing to the plants being placed in newly-prepared soil." Unnecessary cutting or lacerating of the roots should not, on these accounts, be tolerated. The only instance that strikes us at the moment, where a shortening of the roots

by the knife is justifiable, is in the case of some of the cabbage tribe reared from seed in very poor soil: such, having a tendency to throw down tap-roots in search of food, may with great propriety be shortened at transplanting.

In every operation of transplanting the esculent productions of the kitchen-garden, regard must be paid to the preservation of the spongiolets, and this the more so when the operation is to be carried out without checking the growth or vigour of the plant, as in transplanting lettuces at any age. (For reasons, see TRANSPLANTING, FRUIT-GARDEN). Nor should any curtailment take place in the foliage, unless of such parts as may be accidentally broken or bruised during the operation.

In regard to soil, some have gone so far as to recommend a different soil in the garden for its various products; this has long been proved to be not only unnecessary, but absurd. To carry out such views in the cultivation of the parsnip, for example, it would, according to them, be requisite to transport a section of one of the chalk hills of Kent, Sussex, or Hampshire, for their especial use; and for sea-kale, to transport a sand-bank from the sea-shore for a similar purpose. The chemical relationship seems to cease—that is to say, if it ever existed to the extent that plants growing on calcareous soils, or on siliceous ones either, will not grow in other soils deficient in, or actually devoid of, such chemical constituents—as soon as plants are taken under the fostering care of man; and few or none refuse to grow to far greater perfection in good garden soil, than they are anywhere to be found in their natural habitats. The samphire may be an exception to this rule; nevertheless we have had it growing amongst a collection of native plants in pots, in *common soil*, for many years. There has been a great deal too much attempted to be made of the relationship between plants and the chemical constituents of their native soil, by our *flower-pot experimentalists*, as well as of chalking out, according to the rules of latitude, longitude, and altitude, the prosperity of our fruit trees, and their periods of ripening their fruit. To this, reference will be made in its proper place. Meanwhile we say, in a good staple soil,

on a dry bottom, highly manured and well trenched, and exposed to the weather, every esculent man has adopted may be grown, under proper management, to the highest degree of perfection. Fuller details on this subject will be given under each vegetable, &c. discussed.

§ 6.—PROPOSED ARRANGEMENT.

In treating on the culture and management of culinary vegetables, it would, no doubt, be desirable were a classification or systematic arrangement of them established, if for no other end than that of rendering reference to them more convenient. This has been attempted, but never satisfactorily accomplished; nor do we believe such an arrangement possible, from the circumstance of so many of the plants under this head being used for different purposes, and many having no point of union in culture, position in the garden, season of sowing, planting, use, &c.

The following arrangement, so far as it goes, may be useful in this respect, viz. :—

Alliaceous plants, comprehending the shallot, garlic, rocambole, onion, leek, and chive.

Leguminous plants.—Pea, bean, French bean, and scarlet runner.

Brassicaceous plants.—White and red

cabbage, Couve tronchuda or Portugal cabbage, cauliflower, broccoli, Brussels sprouts, savoys, boricoles or winter greens, and sea-kale.

Asparaginous plants.—Asparagus, alisanders, cardoon, globe artichoke.

Spinaceous plants.—Common spinach, New Zealand spinach, and white beet, &c.

Acetariaceous plants.—Lettuce, endive, succory, dandelion, sorrel, tarragon, burnet, celery, mustard, curled and plain cress, water-cress, American cress, winter cress, Normandy cress, Indian cress, purslain, chervil, rape, corn salad, radish, &c.

Esculent-rooted plants.—Carrot, turnip, potato, Jerusalem artichoke, red beet, skirret, scorzonera, salsify, parsnip, Hamburg parsley.

Oleraceous plants, comprehending parsley, dill, borage, thyme, sage, clary, balm, mint, costmary, tansy, basil, savory, marjoram, anise, caraway, coriander, angelica, &c.

Medicinal plants.—Chamomile, elecampane, wormwood, rue, hyssop, and others.

Edible fungi.—Mushroom, truffle, and morel.

Miscellaneous, not referable to any of the above sections, but used in confectionary and domestic economy.—Rhubarb, love apple or tomato, egg plant, gourd, capsicum, marigold, liquorice, rosemary, lavender, horse-radish, &c.

CHAPTER I.

ALLIACEOUS PLANTS.

§ 1.—THE SHALLOT.

Natural History.—The shallot (*Allium ascalonicum* L.) belongs to the natural order Asphodeleæ, and the class Hexandria, and order Monogynia, in the Linnean arrangement. The order Asphodeleæ contains about five hundred and twenty species, the majority of which inhabit the temperate, and even the colder regions, few of them comparatively being found within the tropics. The genus *Allium* (derived from the Celtic *all*, hot or burning) comprises one hundred and twenty-six species, eleven only of which have as yet been found worth cultivation, and of those the subjects now to be treated of—namely, the shallot, garlic, rocambole, onion, leek, and chive—are in most repute. Many of the species are, however, very pretty, and, notwithstanding their unpleasant odour, have found a place in our flower borders. The roots of all the genus are eatable, and those of some—the onion, for example—rank among the most useful articles of food. None of the family are even suspected of possessing deleterious properties.

The shallot is indigenous to Palestine, abounding in the neighbourhood of Ascalon, from which circumstance the specific name, *ascalonicum*, has been given. It is often written eschalot; it was also formerly called scalion, evidently a corruption of Ascalon, from whence it came. It was introduced to Britain in 1548—by whom or how we have no record left.

Uses.—On account of the mildness of its flavour, compared with that of our other cultivated *Alliums*, it is preferred in cookery as a seasoner in stews and soups. It is also much used in a raw state; the cloves or sections of the root, cut up into small pieces, form an ingredient in French salads, and are also sprinkled over steaks, chops, &c. The true epicture, however, cuts a clove in two, and by rubbing the inside of the plate, secures the amount of relish to suit his palate. Shallot vinegar is made by putting six cloves into a quart bottle of that liquid; and when sealed down, it will keep for years. It also makes an excellent pickle. It has been in use since the days of Pliny, who says “the Ascalonian onions are proper for sauce.”

Propagation.—The shallot is easily propagated, each bulb being formed of several parts, called cloves, which, when separated, form each a new plant, affording a peculiar instance of the mode which nature has adopted in fulfilling her laws for the renewal of the species. The shallot, being a native of the warmer climate of Syria, seldom if ever produces seed in Britain, and hence would ultimately become extinct, were this or some other viviparous process not devised, by which they are enabled to continue themselves.

Planting.—The proper season for planting is autumn, either during October or November, as much of the success depends on early planting—a practice recommended by Marshall nearly a century ago, and revived by Henderson, who, in a communication to the Caledonian Horticultural Society (*vide* vol. i. p. 199, of their “Memoirs”), says in reference to securing this crop from the attacks of maggots, “autumn planting is the whole secret.” Subsequent experience has so far proved the correctness of this recommendation.

In light, well-pulverised soils, the cloves or sets should be planted in lines, twelve inches asunder, and the cloves four inches apart. In preparing the ground, after being trenched or very deeply dug, it should be gathered up in ridges of the above distance, and four inches in height. On the top of these the roots should be set, and merely slightly covered. In strong clayey soils, also, after being deeply trenched or dug, draw drills fifteen inches asunder and three inches deep; fill them up to the surface with light sandy compost, upon which set the bulbs, and cover them

with the same, in a ridge-like form, to the depth of two inches. In medium soils, this preparation is unnecessary, as the plant is extremely hardy (at least no frost affects it in its dormant state). A row twenty feet in length will be sufficient supply for a small family: this at the distance given will require eighty cloves, and so in proportion for greater breadths. No bulb should be planted deep; they should rest on the surface of the ground. Their roots proper (for a bulb is not a root) will penetrate the soil in quest of food; and many of them, unlike most other plants, send their roots down in a perpendicular direction (the hyacinth, grown in water-glasses, affords a familiar example), while the bulb is exposed to the influence of sun, light, and air. In shallow soils, planting on ridges has the advantage of affording greater depth than that naturally presented. Knight paid great attention to the cultivation of this plant, and strongly recommended surface, and even elevation planting, assigning as a reason the exposure of the bulbs to the warming influence of the sun during their growing season. By merely drawing a little soil around the bulbs at planting, to keep them steady in their places, the rains of winter, and the necessary use of the hoe, to keep down weeds and preserve the surface open, removes the soil gathered round them, when the bulbs will appear seated on the surface, which is their natural and proper position.

Subsequent cultivation.—Their subsequent management consists in repeated hoeing between the rows, to keep down weeds and maintain the soil open.

Soil and manures.—The soil natural, and consequently best fitted, for shallots, is a rich, deep, sandy alluvial deposit, of itself sufficiently rich without the addition of manure, to which most bulbous plants appear to have a great repugnance. If manure is to be added, in the absence of such conditions, that of the most decomposed description should be employed. It is better, therefore, to plant shallots on ground which has been manured for the previous crop, such as early celery, and in which the manure has been completely incorporated by the process, first of digging up the celery, and afterwards by trenching it two feet or more in depth. If the ground is so poor as actually to require

manure for this crop, then it should be buried in not less than ten or twelve inches under where the bases of the bulbs are placed. The roots will reach it, and their spongiolets collect it at the very time the bulbs most require fertilising aid. Pigeon dung is an excellent manure to be applied to the roots of shallots; and guano and other modern fertilisers may with advantage be applied even on the surface, but not until the plants have made considerable progress in their growth, when they may be laid on during, or, what is better, immediately before rain, so that they may be carried down in a soluble state to the roots. A better way still is to apply them in a liquid state, which will assist in washing the soil from the bulbs, and invigorate the plants at the same time.

Taking the crop, and subsequent preservation.—When the leaves begin to assume a yellowish colour, and droop towards the ground, it indicates that the season of growth has reached its termination. Upon a dry day pull the crop, and arrange it thinly on boards placed so as to be partially shaded from the full sun, for too rapid drying would be injurious to it. While there, protect from wet; and when sufficiently dry for housing, remove the loose and most decayed leaves *only*, and place them on the shelves of the onion-loft, which, at that period, will be unoccupied. Look over them frequently, and remove all decaying bulbs, and the greater part of the now dried-up foliage. Part may be tied up in small bundles of a dozen or two of bulbs each, and suspended from the under side of the shelves, or otherwise if more convenient. Those from which the leaves have entirely separated may be placed thinly on the shelves, or put into nets suspended from the roof. In October or November following, those bulbs which have been best ripened should be selected for planting, and the remaining stock kept moderately cool, well ventilated, and not crowded together. The usual season of their ripening is in July and August: this depends, however, greatly on situation.

List of approved sorts, and their qualities.—There appear to be in cultivation two varieties of shallots—the common and the Russian. The former keeps best; while the latter is considerably larger, and milder in flavour. A fair-sized bulb of the former, when ripe, should measure

about three inches and a half in diameter, and the latter about an inch more. The *Allium ascalonicum*, var. *majus* of botanists, is, we believe, identical with the Russian. A long-keeping variety—said to keep for two years, is spoken of. We have had this sort, at least one so called, but could never see any difference in it, either as to keeping, or in size or form, from the Russian, with which we believe it to be identical.

Insects and diseases.—The principal, if not the only, disease the shallot is liable to is the attack of a maggot, generally found under the bulb, which soon becomes covered with a mouldy appearance, and speedily afterwards rots away. This is probably not different from *Anthomyia ceparum*, Meig., the common onion-fly, which see. Planting on the surface, or indeed on raised ridges, as recommended by Knight, had for its chief object the prevention of this disease. Imbedding the bulbs at planting in finely-sifted charcoal has also been recommended. In our present state of information regarding the habits of this insect, there can be no doubt that collecting the plants upon their indicating the first symptoms of the disease, and burning them, will have the effect of greatly reducing the number of insects in succeeding years. Spirits of tar dug into the ground at planting, and salt, soot, nitrate of soda, watering with lime-water, as soon as the leaves begin to flag during the heat of the sun, which is indicative of the first attack, as well as urine and guano water copiously applied, have all in their turn been repeatedly tried; and wherever a marked benefit was discovered, it in all cases depended on the remedies being applied upon the very first appearance of the disease.—(Vide art. ONION.)

Botrytis destructor (Berk) makes its first appearance as a white mould or mildew upon various kinds of Alliums, and often destroys the whole crop, particularly shallots. On its first appearance, the infected leaves should be cut off and burned: all other attempts at destroying it in a more perfect state appear to be hopeless.

General Remarks.—Shallots, till within these few years, were little cultivated in Scotland, excepting in some of the first-rate gardens. In the markets, they were unknown, the onion and the leek being the only alliaceous esculents in demand. They have only to a limited extent found their way into the gardens of cottagers and small families even in England, a circumstance to be regretted, as they are exceedingly wholesome, communicating an agreeable flavour to many of our commonest dishes; and the supply for a family can be grown on a very limited extent of ground compared with the onion or the leek. All over Europe they are much more extensively cultivated and esteemed, and in some countries rank higher than the onion, their near ally. In France they are called *Echalotte* or *Ail sterile*; in Germany, *Schalotte* or *Aschlauch*; in Holland, *Chalot* or *Sjalotte*; in Italy, *Scalogni* or *Cipolle malige*; in Spain, *Escalonia* or *Chalote*; in Denmark, *Scalotlogen*; in Sweden, *Chalottenlok*.

A curious instance of the transmutation of the shallot into the onion has recently occurred

in the grounds of Messrs Hardy and Sons, Maldon, Essex. "The transmuted shallots, or rather onions, raised by us from shallot-seed, did not produce potato-onions, as it was presumed they might, but numerous heads of seed varying from ten to twenty from a single bulb. They certainly possess the qualities of both onions and shallots in flavour, the size of the onions, and the fact of their being divisible like shallots; the blade is very narrow, partaking of both species; the seed is small."—*Messrs Hardy's Letter*. Plants have been raised from this transmutation, and grown in the garden of the Horticultural Society of London, and the following are the results, as given in the Journal of that Society:—"The seed was sown on the 20th March, and produced a mixed race, varying in size, form, and colour. Some were regularly formed by concentric layers like an onion. Sometimes the formation consists of two closely conjoined, compressed, but separate bulbs, and frequently clusters are produced very like shallots. The colour, in some, approaches that of the silver-skinned onion, in others the blood-red, but the generality are reddish brown. They are strong flavoured, and have the appearance of being good keepers." They, however, want uniformity in size and colour, but, by judicious selection, a useful, sound, keeping variety may probably be produced. The circumstance is curious, and strongly favours opinions at present attracting considerable attention, and which may ere long overturn the long-established doctrine of the permanent distinctions supposed to constitute what is called species in plants.

Shallots are sold by weight. One lb. contains about twenty ordinary-sized bulbs.

§ 2.—GARLIC.

Natural history.—Garlic, *Allium sativum* (from *Sativum*, cultivated), L., belongs to the same natural order, and class and order in the Linnaean arrangement, as the shallot. It is a native of Sicily, the south of France, and most of the south of Europe, being found growing in meadows, pastures, and waste places. It has been cultivated in this country since prior to 1548. Old Thomas Tusser notices it as cultivated in the time of Queen Mary. His twelfth verse for the month of November says, "Set garlic and beans at St Edmund the King."

Uses.—The roots of garlic (the only parts used) held a place in most of our early pharmacopœias, but, like many other of our vegetable medicines, have been little used by modern practitioners. Sydenham recommended its use in the first stages of dropsy, as being a warm, strengthening medicine. He also recommended it as a powerful resolvent, "for which purpose," Phillips informs us (vol. ii. p. 24), "he was led to make use of it in the confluent smallpox. His method was to cut the root in pieces, and apply it, tied in a linen cloth, to the soles of the feet, about the eighth day of the disease, after the face began to swell, renewing it once a-day till the danger was over." It is held a sovereign remedy

against intestinal worms by many a good housewife at the present day, cloves of it being steeped in whisky, and administered in the morning to the patient fasting—a remedy probably founded on the experiments made by Rosentein and Tissot, who say that garlic “is capable of expelling worms, especially the *tenia*.” From the earliest ages it has been employed in medicine as well as for culinary purposes. It is much used in foreign cookery, especially in the south of Europe, confirming what Haller says of it, “that the inhabitants of all hot countries are fond of garlic.” In many parts of the Continent the peasantry eat their brown bread with slices of garlic, which imparts a flavour agreeable to them; but in the midst of a garlic-eating people, they are well off whose sense of smell is most slightly developed. In Britain it is seldom employed as a culinary ingredient, and then seldom served up in a solid state, the cloves being put in a small bag, and left in for a short time during cooking, and then taken out when the necessary amount of flavour has been communicated to the dish.

The mode of propagation, season of planting, subsequent culture, soil, manures, diseases, insects, taking up the crop and subsequent preservation, are all identically the same as for shallots.

Approved sorts and their qualities.—There is one sort only cultivated in Britain as a culinary plant—the common garlic. Phillips, however, says, in “History of Culinary Vegetables,” vol. ii. p. 26, “Besides the common garlic, *Allium sativum*, the African garlic, *Agracile*, is now cultivated by our gardeners. This,” he continues, “has been erroneously termed Jamaica garlic, from the circumstance of the seeds having been sent from Jamaica to England.” It is not a native of the West Indies, but was brought from Africa to Jamaica, and is the same described by Pliny (book 19, chap. 6), which he says grows larger than the other garlic. He (Pliny) tells us that this kind of garlic was never planted in level ground, but on little hillocks like mole-hills, and that, as soon as they had shown their leaves, the mould was taken away from them; for the oftener they were laid bare, the larger the heads would grow. We make this reference, *first*, to show that what was regarded as a new feature in shallot-culture brought out by Knight, and published in the “Horticultural Society’s Transactions,” vol. ii. p. 98, was the usual mode of cultivating its near kinsman, the garlic, in the days of Pliny; and, *secondly*, to say that of this Jamaica garlic of large size we know nothing. Where attention is paid to culture, the common garlic will attain a size $7\frac{1}{4}$ inches in circumference each bulb; whereas, if grown, as it usually is, in the most negligent manner possible, it does not attain half that size. More attention is paid to its cultivation on the Continent than with us, in consequence of its being so much more in demand; and hence imported bulbs are much larger than those of home growth. In Italy it is known by the name *Aglio*; in Holland, *Knoflock* or *Look*; in France, *Ail*; in Spain, *Ajo*; in Germany, *Knoblauch*; *Alho*

in Portuguese, *Tschesnok* in Russian. In Wales, most of the alliaceous esculents have been and are more generally grown for domestic use than in any other part of Britain. Worlidge, writing early in the seventeenth century, speaking of that principality, says, “I have seen the greater part of a garden there stored with leeks, and a part of the remainder with onions and garlic.”

Twenty ordinary-sized bulbs weigh one lb.

§ 3.—ROCAMBOLE.

Natural history.—Rocambole, *Allium Scordoprasum* (from *σκοποδον*, garlic, and *πράσον*, leek, as if it combined the garlic and leek), L., belongs to the same natural order, and class and order in the Linnæan arrangement, as the last. It is a native of Denmark and many other parts of the north of Europe, and appears to have been early introduced to Britain, as we find it mentioned by Gerard in his “Herbal” as a cultivated plant in 1596.

Uses.—It is used for nearly the same culinary purposes as the shallot and garlic, is milder in flavour than either of them, but is employed to a very limited extent even in families of the highest order.

Mode of propagation, &c.—Its mode of propagation is the same as that of garlic and shallot; only, as it sometimes produces cauline bulbs—that is, small bulbs upon the stem—they are, in cases of a deficiency of underground bulbs, used as a substitute both for use and planting. The whole routine of culture, preservation, &c., is the same as for the two last.

Varieties, &c.—There is only one sort cultivated in Britain.

It is to be met with in Covent Garden market in small quantities. In the Continental markets it is rather more abundant, and is, as a consequence, more employed in cooking. The French call it *Ail d’Espagne*; the Italians, *Scorodopraso*; the Germans, *Rocambollem*; in Holland, *Wile Knoftook*; in Spain, *Especie de Ajo dulce*.

§ 4.—THE ONION.

Natural history.—The Onion, *Allium Cepa* (from Celtic, *Cep*, head), L., belongs to the same natural order, and class and order in the Linnæan arrangement as the last three. Its native country is as unknown as is the birthplace of Homer. Spain has been named; that is, however, highly improbable, as the plant has been known and used as an article of food from the remotest ages of antiquity. Of one thing we are certain: it constituted an important article of food long before the exodus of the Israelites out of Egypt; for among the complaints made to Moses in the wilderness was, that they were deprived of the leeks, onions, and garlic, of which, said the murmurers, “we remember we did eat

in Egypt freely.”—*Numb.* xi. 5. Egypt is to this day famed for the superiority and sweetness of its onions, in comparison with those of Europe—a result, by the way, with which climate may have much to do, as those of Portugal are much more palatable than the same variety grown in Britain; and there is an evident difference, in respect to the mildness of flavour, between those grown in Cornwall and in the Highlands of Scotland. The onion must be a native of the East; and as mankind and civilisation travelled westward, so they would bring with them this ancient and popular pot herb. The compiler of the last edition of the “*Hortus Britannicus*,” whose means and industry in research were undoubtedly great, neither gives the date of its introduction, nor states its native country. It has, however, been an inmate of our British gardens as long as they deserve the appellation. Pliny, who mentions, in book xx. chap. 5, all the countries from whence the Greeks as well as the Romans procured different varieties of this plant, says he could not discover that they ever grew wild.

Uses.—The uses to which the onion is applied in domestic economy are so many, and of so varied a character, that a reference to a cookery-book would be required to discover probably one-half of them. Our present purpose may be served by stating that, when fully grown, they are used stewed alone, and also boiled and roasted. In their young state, from the time they are as large as an ordinary needle, until they attain the height of five or six inches, they are used in mixed salads, and for this purpose they are sown once a-week throughout the season. When about the size of a writing-quill, they are devoured in astonishing quantities by the humbler classes, who eat them raw, with bread and butter, or with bread and cheese. Even when fully grown, the labourer finds a wholesome relish in them, when cut into transverse slices and eaten in the same manner. In many parts of the Continent the humbler classes of artisans bring with them in the morning a small canvass-bag, containing a huge slice of brown bread, a large apple, or a moderate-sized onion. This homely fare forms his sustenance throughout the day; and he devours it with as much gusto and satisfaction as the higher-fed English labourer swallows his slice of home-baked bread, with its usual accompaniment, a rasher of raw bacon; while the Caledonian of the same status munches his piece of oat cake (*without kitchen*), and washes down the dry morsel with a draught of *Adam's wine*. The Scot is not a vegetarian, and cannot be persuaded to eat *green meat*; and here, with all his shrewdness and economy, he is at fault. We hope our countrymen have not been led away by what the author of the “*Gryte Herbal*” saith hereon:—“The onion being eaten, yea, though it be boiled, causeth headache, hurteth the eyes, and maketh a man dim-sighted; dulleth the senses, engendereth windiness, and provoketh over-much sleep, especially being eaten rawe. Being rawe, they nourish not at all, and but a little though they be boiled.”

The witty and satirical Dean Swift says—

“This is every cook's opinion,
No savoury dish without an onion;
But lest your kissing should be spoiled,
Your onions should be thoroughly boiled.”

Our immortal bard did not overlook their tear-bringing property. He says—

“If the boy have not a woman's gift
To rain a shower of commanded tears,
An onion will do well.”

Mode of propagation.—The general mode of propagating the onion is by seed. There are a few of the species, however, which do not ripen their seeds freely, and these are propagated by other means. These will be noticed in their rotation.

The onion being with us an annual crop, the seed system of propagation is followed, and those varieties which are propagated otherwise are, in general, dependent on the bulbs which form on the top of the stem, as in the case of what is called the tree-bearing onion, from its producing viviparous bulbs at the top of the stalk, or in that of the potato-onion, which produces offsets under ground, rendering them capable of being continued without the aid of seed. Sometimes, again, the very small and imperfectly-formed bulbs are chosen for re-planting, and from these fine crops of large well-formed bulbs have been produced. There are other modes of propagating the onion, but the processes of them are so truly scientific as not to come within the sphere of profitable culture. Although usually treated as an annual when grown for its bulb, or as a biennial when cultivated for seed, it is, in fact, naturally a perennial, and continues itself by offsets as well as by seed. The seed usually germinates in about a fortnight in ordinary mild weather.

Planting and sowing.—The season for sowing varies so much from the difference of the natural seasons, the wide differences of soils, climates, and situations, that no precise date can be given applicable to all places and circumstances. In our early days the 2d of February was looked upon as the advent of onion-sowing; of later years it has been the middle of April before the operation could be commenced—a delay occasioned solely in consequence of the ground⁴⁵ being either frozen or too much saturated by wet. This delay, however, has less influence on the time at which the crop comes to maturity than might be at first

supposed. Early sowing has, nevertheless, its advantages, one of which, and an important one too, is, that germination takes place slowly, the roots take the advance of the leaves, and, by their doing so, they are stronger and more numerous; and, consequently, when the invigorating effects of the advancing sun begin to act upon the foliage, they are in a condition to provide and throw into the system of the young plant a much greater quantity of nourishment than they could do if vegetation commenced in both simultaneously, which would be the case if not sown before the middle of April, when the air becomes warmed by solar influence. Another advantage has been stated as arising from early sowing, which is the greater strength communicated to the plant, and hence its greater ability to resist the attacks of insects. This view seems strengthened in the case of autumnal-sown onions, which seldom are attacked by the grub, because they are not only stronger, but have attained a greater degree of pungency before the season at which the insects are hatched. Late-sown onions have of late years often been cut off by spring frosts just as they were coming through the ground, or when they are about a couple of inches in height. The more rapid process of vegetation induced by those warm sunny days we now so often experience during the month of April, makes the young plants rush up rapidly, and in this tender state they fall a ready sacrifice to the sharp frosts which so often in the mornings succeed those warm sunny days. Where vegetation proceeds more slowly, and where it influences the roots sooner than the tops, the plants not only become better inured to the cold, but, should it even prove severe, the strength thrown into the plants by the roots enables them much better to resist its effects.

No positive date can be given as to the day or week, nay, even month, that the operation should be performed, suitable to all soils, situations, and circumstances; the condition of the soil should, however, never be disregarded. In this, as in all other cases of seed-sowing, the soil can never be too dry, nor too much pulverised; and this is more especially the case in all cold, damp, and strong clayey soils. In the neighbourhood of towns, where the

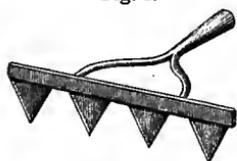

soil is highly enriched, and contains a large amount of humus, and where, as in the case of commercial gardens, it is thoroughly wrought by repeated trenching and digging, the beginning of February may be taken as a good time for sowing, provided both the weather and soil are in a fit state. In all cold elevated situations, and where the soil is wet and in an imperfect state of culture, then the middle of March will be a more proper season, and in the worst situations of all, the beginning of April.

Autumnal sowing has not only the advantages stated above, but also that of affording during winter a supply of young onions for salad purposes, as well as for being used in French cookery, particularly in the artistic preparation of that not-to-be-despised viand, a properly cooked rump-steak, which is amazingly improved by being served up covered with young onions, cut up into the smallest possible fragments. Onions are also sown in autumn, say about the middle of August; and where they withstand the winter, they are transplanted in March or the beginning of April, according to the circumstances of soil, &c., stated above, in lines a foot asunder, setting the plants six inches apart in the row. These, having the start of the spring-sown crop, bulb earlier, furnishing a supply after those from the onion-room have been consumed, and carrying on the supply till the spring-sown crop arrives at maturity. The best formed and best ripened bulbs of the autumn-sown crop are selected, and reserved for winter use, and fill the shelves of the onion-room long before the general crop is fit for storing. Many adopt the autumn sowing and spring transplanting, believing the onions so produced keep better than the others. This may be accounted for by their being more thoroughly ripened, during July and August, than the general crop, which ripens at a much later and more unfavourable season. We ought, however, to observe, that all autumn-sown crops of this plant, intended to arrive at maturity, should be transplanted.

The best mode of sowing the onion is in drills from nine to twelve, and even fifteen inches apart, according to the soil, and the size the crop is likely to arrive at. In poor soils, where the

bulbs usually do not much exceed the size of a large walnut, the former distance will be sufficient; when they are to attain their fullest size, which they will do in rich, well-wrought ground, and in a medium climate, then the latter distance will not be too much, because the foliage requires room for development, and a full exposure on all sides to the influences of light and air, without which they could not elaborate the necessary amount of sap required for the perfect enlargement of the bulbs. This is clearly demonstrated in the case of onions sown thickly in a bed, and allowed to remain so, compared with the same sort grown in the drill manner, and allowed sufficient room. The latter will bulb, the former will not at all; but at the termination of their growing season, they will resemble more the character of the leek than the onion. In this state, they justly come under the denomination of *sybo* or scallion, or imperfect onion—that is, having leaves and stalk, but no bulb. In forming the drills, after the ground has been broken by being raked over deeply, and reduced to a pretty fine state of pulverisation, the line is stretched from end to end of the ground, and the drill opened with the corner of a sharp clean draw-hoe, the face of which is directed towards the line, the operator standing on the side still to be drilled, by which means the drills are left entire and open. Various contrivances have been employed to economise time in this operation. The drill-rake (fig. 1) is one of the simplest and most efficient, and is constructed of a headpiece, like that of a common rake, only double the size, into which broad flat wooden

Fig. 1.

DRILL-RAKE.

teeth being set at different distances, to adapt it to different crops, according to the distance the rows are to be apart, these pieces being screwed together at each end; or if more than three drills are to be drawn at once, a third screw is placed in the middle. Others use a head perforated

with small holes, one inch apart, into which the tops of the teeth are set, and fixed at any required distance. We use, attached to Sievewright's cultivator, which runs on a small wheel behind and another in front, a transverse iron bar perforated with holes, cut with female-screws within, to receive the tops of the drill-forming teeth, which are cut with male-screws, so as to work in the others. By this means we can draw at once six or eight drills, and at any distance required: one man draws the machine, and another guides it behind. In either case it is necessary to set off the first drill with a line, afterwards the drill-tooth on the right-hand side should be made to travel over the last drill formed. This keeps the drills straight and equidistant. Such appliances work, however, best in light dry ground, and in such as are in a highly cultivated state, and free from stones.

Onion-seed is in general sown too deep; 1½ inches is amply sufficient, and even one inch has been found by some growers to be better. Abercrombie, were it not that he recommends broadcast sowing (that is, promiscuously over the whole surface), is correct as to depth. He says, "sow broadcast equally over the rough surface, moderately thick, and rake in the seed in a regular manner." Some good cultivators, after the ground has been properly dug or trenched, lay *very rotten* manure over the surface, and on this they sow the seed, covering it slightly with earth from the alleys. This would be a very excellent plan, could the seed be disposed of in lines, and kept in them during the process of covering. All broadcast sowing, in the case of such crops, is far behind the present state of high cultivation: it is, however, not ill adapted to the limited scale of a manse or cotter's garden. The principle of deeply stirring the soil, and placing on its surface the necessary manurial application equally over it, is perfectly correct. It is thus in the most favourable position for its fertilising properties reaching the points of the roots, as it will be washed down to them by the rains; and they are the parts to which enrichment, to be useful, should be applied. The London market-gardeners sow their principal crop in February or the begin-

ning of March, on beds five feet wide, and in the broadcast manner, covering the seed with soil from the alleys. They rake the ground, and draw a wooden roller over it.

The mode of planting depends on circumstances—namely, whether young plants of the current year, those of last autumn's sowing, or the smallest bulbs selected from the preceding crop, are to be operated on. In the case of the former, the seed should be sown about the beginning of February, in light, rich, sandy soil, placed over a hotbed of moderate temperature—say of 45°; or they may be sown in what is called a cold pit or frame—that is, a structure having no artificial bottom-heat, but depending entirely on solar heat transmitted through a glass covering. Towards the end of April, if the weather has set in favourable, the young plants should be carefully taken up, without injury being done to either their tender tops or equally tender fibres, and transferred to the open quarter of the garden—the ground being previously prepared by trenching or deep digging, and in a high state of enrichment from the manure applied to the preceding crop—say celery. The process of planting in most cases—in this one in particular—is most advantageously carried out by proceeding in the following manner; and as it is in the main applicable to the planting of all other crops, it deserves, for the benefit of amateurs, a clear explanation:—The ground being, it is presumed, already trenched and manured, commence at one side of the quarter or piece of ground to be planted; break down the surface with a wooden rake to a moderate evenness of surface, and freedom from clods and stones. Stretch the garden line from end to end perpendicular to the cross walks, or parallel with the adjoining crops or walk, so that the rows, while growing, shall appear as if laid down corresponding with other straight lines, as if they had been drawn by a parallel ruler; for nothing looks worse, when viewing the crops in a garden from the principal walks, than to see the lines of crops in the quarter or division nearest to the point of observation running five points to the east or south, while those in the piece adjoining are running as many points in an opposite direction. This being done, beat the sur-

face of the ground, for about the breadth of nine inches, gently down with the back of a spade, so that the whole shall be smooth and level. Commence at the end of the line, or at different points, according to the number of men employed. The young plants are laid in shallow boxes, covered over with moss, or any other light covering sufficient to exclude the air while they are yet unplanted; each man having a box, and no more plants brought out than can be planted within an hour or so. They are then to be set in holes made by a small blunt dibber, about as thick as the little finger, and not above an eighth of an inch deeper than where they have been growing, and at the distance of 5 inches apart in the row. If, however, there is an apprehension of the maggot, or of other injuries befalling them, they may be set at double thickness, as it will be better to thin out in May every alternate plant, than to have to make up deficiencies. When the first row is planted, the line should be removed; and in doing this some caution is necessary, lest, in its removal, any of the plants be withdrawn from their places. If the line is gently drawn from the plants, rather than drawn upwards, little danger of this need be apprehended. A better way, however, is, when the process of beating the ground is finished, the mark of the line being still quite visible, to lift it at once, and set the plants along the marked line. There is an unfortunate pertinacity amongst a certain class of even young men to do nothing without a line. The man who cannot or will not plant a row of young onions as straight as an arrow by the mark of the line thus made, should be furnished with a pair of eye-protectors, and recommended to the nearest road-surveyor, to try his hand at macadamising. When the first row is finished, proceed in like manner with the next, and so on, watering, if the weather is dry, every three rows, as the work goes on. By this means the soil will remain untrodden, as it will be pointed over—that is, dug shallow as the operation proceeds. The only care to be taken during the operation is, that the plants be not set too deep (*vide supra*). The process of transplanting autumn-sown onions is precisely the same as above, except in so far as they, at the period of

transplanting, are much larger—say from the size of a crow-quill to that of an ordinary writing one: the roots are proportionably larger also. The ground being prepared as above, and the line stretched out, a shallow notch in the back part—that is, that next the line—should be cut somewhat oblique, and *no* deeper than the exact length of the roots. The young plants should be carefully taken up, with their fibres quite entire (on this much of the success depends); and to facilitate the operations, the ground in which they are growing should be loosened deeply with a three-pronged fork. They should also be placed in shallow boxes (trays), and protected from the sun and air while out of the ground. The whole thus far being in readiness, the planter arranges the plants in a slightly slanting direction against the oblique bank, taking care that no part of the plant is covered with soil save the roots; and while the arrangement of the plants is going on, the roots are covered as they are placed by pushing a little of the finest soil against them with the hand. The plants should be allowed the same distance as those above. When they are all arranged in the first line, some more soil is placed over the roots by the spade, the line removed, and a fresh row marked out. We often, in our own practice, and operating on a very light soil, prepare the ground as we have described above; but instead of cutting out a slight notch, we lay the plants flat down on the smooth-beaten surface, and place over the roots a little well-pulverised soil. This is a good plan at an advanced period of spring, for should a warm shower or two fall soon after planting, the plants will rise themselves to a perpendicular position, having no part under the surface except the roots. And this is desirable, for if they were deep planted, their bulbing would be prevented, at least to a great extent.

The third mode of raising onions referred to above, is by small bulbs selected from the previous crop, and which may be about the size of a hazel-nut. Some sow expressly to secure such (*vide infra*). This practice is not noticed as a novelty, for it has been more or less adopted from time immemorial. Its true object is to obtain larger onions than the coldness of our climate enables us to do with spring-sown ones, and it, therefore, may be worth

the attention of those who live in high and cold situations, even should they purchase the small ones to plant, which may readily be obtained from any respectable nursery or seedsman. The earliest written mention deserving much credit we have met with of this practice is recorded in “*Systema Horticulturæ*,” by Worlidge, who practised towards the beginning of the seventeenth century. The late Mr Knight revived the practice, and his papers in “*The Horticultural Transactions*” led others to speculate in the same way. A quotation from that high authority will be quite sufficient for our present purpose. After some preliminary remarks on bulbous and other perennial plants having the property of accumulating in one season the material that composes the leaves and roots of the succeeding season, he proceeds: “This reserved sap is deposited in, and composes in a great measure the bulb; and the quantity accumulated, as well as the period required for its accumulation, varies greatly in the same species of plant, under more or less favourable circumstances. Thus the onion in the south of Europe acquires a much larger size during the long and warm summers of Spain and Portugal, in a single season, than in the colder climate of England; but, under the following mode of culture, which I have long practised, two summers in England produces nearly the effect of one in Spain and Portugal, and the onion assumes nearly the form and size of those thence imported. Seeds of the Spanish or Portugal onion are sown at the usual period in the spring, very thickly, and in poor soil, generally under the shade of a fruit tree; and in such situations the bulbs in the autumn are rarely found much to exceed the size of a large pea. These are then taken from the ground and preserved till the succeeding spring, when they are planted at equal distances from each other, and they afford plants which differ from those raised immediately from seed only in possessing much greater strength and vigour, owing to the quantity of previously generated sap being much greater in the bulb than in the seed. The bulbs thus raised often exceed considerably five inches in diameter; and, being more mature, they are with more certainty preserved in a state of perfect

soundness through the winter than those raised from seed in a single season." Knight's mode of planting these was the same as our own—namely, to set them at ten inches from each other, or when in lines, twelve inches apart and eight inches in the line, the ground being prepared as above recommended for spring and autumn sown crops—setting the bulbs, however, on the surface, and drawing as much soil over them as will maintain them in their places until they attach themselves by their roots to the ground; after which, as in the case of shallots, &c., already noticed, the earth is removed from them, and the bulbs are exposed to air and light. This practice, or that of saving all the very smallest from the previous crop, has been followed by some of the market-gardeners round London for ages. It is rarely practised in private gardens—why, we know not.

The fine large Portugal onions which we see in the shops are imported from that country annually. They are indispensable in the kitchens of the great, being much milder, as well as being of a much larger size, than can be produced in any quantity in this country. They are grown upon a somewhat similar principle to that noticed above; the method is sufficiently interesting to warrant our making the following quotation from "The Transactions of the Horticultural Society," vol. iii. p. 68: "Sow the seed very thinly in November or December on a moderate hotbed in a warm situation, with a few inches of rich light loam upon it, and the plants protected from frost by mats and hoops. In April or May, when they are about the size of a large swan's quill, they are transplanted on a rich light loam well manured with well-rotten dung. The mode of transplanting is particular. The plants are laid flat, about nine inches asunder each way, in quincunx, the beard (fibres) of the root and part only of the plant covered with very rich mould, well mixed with two-thirds of good old rotten dung. This compost is slightly pressed down on the plant; water is given, when the weather is dry, until the plants have taken root. Subsequently, the earth is occasionally broken around them by slight hoeing, in which operation care is taken not to wound the bulb. Weeding is diligently

attended to, and the watering continued according to the state of the weather. In Portugal the means of irrigation are easy, the effects of which are particularly beneficial to the onion; for, by letting the water filter or pass through small heaps of dung placed in the alleys of the beds, a very rich liquid flows in upon the plants. The dung, as it is exhausted or washed away, should be renewed, and the water must be checked in its current, so that it may gently spread over the surface." This mode has been successfully tried in some parts of England upon very warm borders. In our present state of advancement we would apply liquid manure in a much more convenient manner, and there is no means of enrichment so beneficial to the alliaceous tribe as administering it in a liquid state.

We have already observed that the drill system is preferable to the broadcast order of sowing. This, however, applies more to private gardens than to commercial ones, or even to those whose onion-bed does not exceed two or three square yards. Although, in many of our first-rate market-gardens, the drill system is pursued, still by far the most adhere to the old plan of dividing the ground into three-feet-and-a-half or four-feet beds, and sow promiscuously over them, and trust to hand-weeding for the suppression of weeds. In this they do not err, because, from the time the young plants are three or four inches in height (up to which time they do not injure each other), a constant system of thinning is going on—the thinnings meeting with a ready sale in the market; so that the crop is in due time sufficiently thinned to enable those left to attain their full size;—sowing in drills is therefore to them of less importance. We hold it essential in all well-kept private gardens. Treading the ground after the seed is sown is advisable in very light soils; if dry at the time, it tends to consolidate it to a proper consistency. To do so, however, in strong soils, particularly when wet, is injurious. It cakes the surface, and renders it more difficult for the young plant to push its way through. To those who prefer the broadcast mode of sowing in beds, a better plan cannot be recommended than that practised by Mr Smith of Pitfour. The ground being dug, the manure is laid

on the surface in a very decomposed state. When levelled, the seeds are sown, and pressed down by the back of a rake; a little fine soil is thrown over from the alleys. When the plants are about an inch above ground, they are dressed every three or four weeks with a mixture of guano and charcoal-dust, to the extent of a handful to each square yard, one-third being guano, choosing moist days for applying it.

Before quitting the subject of sowing and planting onions, we may remark that, however sanctioned by the practice of ages, the custom of sowing other crops along with the onion, considered as a general one, is erroneous. The ancients believed that some plants had a sympathy with, or antipathy to each other. They also set great importance on sowing, planting, gathering the crops, &c., at certain stages of the moon. Both these doctrines we have been taught from childhood to regard as absurdities; but, strange to say, something about the latter has been very recently revived, and the greatest horticultural oracle of the age has thrown out a hint that we should henceforth desist from covering our cucumber beds at night, that the plants may receive the full influence of Luna's silvery beams. As regards the former also, while we must continue to consider the explanation utterly unfounded, the chemistry of plants has shown us that, in some cases at least, the practice might be less absurd than at first sight appears; for it is conceivable that two species of plants might draw essentially different nourishment from the soil, and that each might be withdrawing from it something, the excess of which was hurtful to the other—each thus indirectly aiding the healthy growth and full development of the other.

Returning, however, to the sowing of onions in conjunction with other plants—a little lettuce-seed may be thinly scattered over the ground after the onions are sown, as the plants will come off soon, and many of them may be transplanted; but the old practice of sowing leeks, parsley, or carrots along with onions, is doing justice to neither. It is, however, worth remarking that, in soils where carrots are destroyed by grub, they often, when sown along with onions or leeks, escape their attacks.

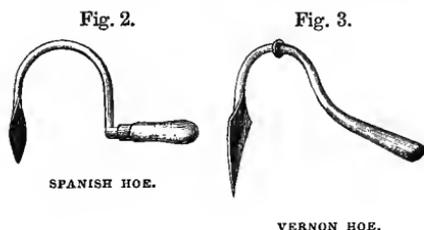

The London market-gardeners sow in beds five feet wide, and in the broadcast manner. They cover with soil from the alleys, by throwing it over the seed. The beds are raked over with a wooden rake, and a light wooden roller is drawn over the surface, being more expeditious and proper than foot-treading, for which they have no time. Such ground as theirs is much benefited by rolling, as it is so soft, spongy, and full of humus, from the enormous quantity of manure which is at almost every change of crop trenched into it.

The number of roots required to plant any given space will be readily ascertained by referring to the distances given above.

The quantity of seed required to sow in the broadcast manner a bed 4 feet by 24, when all or part of the crop is to be drawn young, is two ounces; but for the same space, if the crop is intended to come to maturity, half that quantity will be sufficient. According to the drill system of sowing, a third less in both cases will be ample. There is a great mistake in thick-sowing: the plants become weak and drawn up at first starting; and thinning, either in time or to a sufficient extent, is too seldom attended to. This should have been placed as one of the first items in the very sensible, but satirical, directions given by the author of a series of papers in "The Gardeners' Chronicle," entitled, "How to mismanage a garden." In stating, however, the quantities of seed necessary for sowing a given space, we may state, once for all, that our quantities are given on the presumption that the seed is good. For means of ascertaining this, *vide* article PROPAGATION BY SEED.

Subsequent cultivation.—The subsequent culture of this crop consists in keeping the ground between the drills perfectly clear of weeds by repeated hoeing—not waiting, however, as some do, till the weeds become the principal crop, requiring no small skill, and a vast amount of labour, to remove them, leaving the young tender onions exposed to the full rays of the sun, or perhaps to a frosty May morning, either of which they are in a very unfit state to withstand, having been hitherto snugly sheltered under the protecting shade of groundsel and chick-

weed. The purpose of hoeing is twofold, in all cases save that of a gravel walk, whereon such an operation should, if possible, never be allowed. Hoeing keeps down weeds while in their cotyledon state, that being the most proper time to attack them; it keeps the surface of the ground open, and renders it pervious to the rays of heat and to air. Weeding only removes the evil after it has too long existed; in the process the ground is trodden to a hard surface, and unless immediately loosened by the hoe, it is rendered next to impervious to heat and air. The hoe, therefore, should be used at once, and one operation thus be made to do, instead of two. The best hoe, when deep-stirring the soil between drilled crops is performed, is the Spanish hoe, fig. 2, or the Vernon hoe, fig. 3; the former

an implement much employed in the West Indies for deep-stirring the sugar crops. The flat or common hoe is only useful for cutting down weeds; and as it is in general used, it does do little more; whereas the deep-stirring of the soil is of the greatest importance, and can only be efficiently performed by such an implement as the hoe referred to. Here we see the great advantage of the drill system over the broadcast method of sowing. Thinning the crop should be attended to as a principle, and, unless in petty gardens, dependence should not be placed on the removal of superfluous plants for daily consumption; it is better to thin the general crop, and leave a row or two for daily use. The London market-gardeners thin their broadcast sown crops as soon as they appear above ground, by using small 2-inch hoes, kept exceedingly sharp and clean.

Soil and manures.—Onions require a deep, rich, mellow soil, always kept in a high state of enrichment by the application of such stimulants as guano,

blood, salt, soot, the offal of a slaughterhouse, superphosphate of lime, at the time of sowing. But where the ground has been highly manured for the previous crop, such as celery, it is better to depend on that, with the addition of liquid manure where it can be applied, than on the recent application of stable-yard manure, unless in a state of great decomposition. The London growers, however, seem to put all danger from insects at defiance, and manure heavily with the strongest dungs, such as cow manure, nightsoil, &c. They are seldom troubled with onion grubs, or, indeed, with any other; and this, they assert, is entirely owing to their ground being turned so frequently and so deeply over—thus, probably, preventing the insects from undergoing the various transformations which most of them have to pass through. Neither are they very particular as to the change of soil, or what is called the rotation of crops, for we have seen abundant crops of onions on ground from which three and four successive ones of that vegetable have been taken. To ordinary cultivators this may appear anomalous, as it is also contrary to the principles of vegetable physiology: it does, nevertheless, occur in their practice, and they ascribe it simply to their ground being in the highest state of fertility, and in the highest state of cultivation; and they maintain that private gardens are neither the one nor the other.

Forcing.—The onion is forced during winter in many large gardens, being used in a very young state as an ingredient in salads. The seed is sown thickly in shallow boxes in light sandy soil: rich soil is not necessary, as the crop is gathered when the plants are little larger than an ordinary-sized needle. A very small quantity only is daily required, to give some idea of which we may mention that, when gathered and washed (for all salads should be prepared before leaving the garden—but of this more anon), with the leaves and fibres entire, the supply for the day will be a small bundle about the size of a man's finger. Boxes, therefore, or square earthenware pans (the latter of which we use), about 18 inches square and 4 inches deep, if sown every third or fourth day, and placed in a pit, or on a suspended shelf in a vinery where the temperature ranges from 45° to 60°, will be a very fitting

place for them. There are several modes of forcing onions, so as to have bulbs for use between the time those wintered in the store-room are finished, and that at which they ripen in the open air; but the trouble and expense attending these methods might, we think, easily be spared by adopting the best modes of keeping the previous crop, and cultivating more largely that excellent sort known as the potato or underground onion (which see).

Taking the crop, and subsequent preservation.—The season of ripening, like that of all other crops, depends greatly on circumstances. This is first indicated by the leaves turning yellow and beginning to fade; and in the smaller bulbs, by the leaves dropping off altogether, which shows them to be perfectly ripe. The larger specimens, on account of their containing a much greater amount of elaborated sap thrown into them by their larger and more numerous leaves, do not indicate ripeness so soon, and a certain class, from over excitement, and grossness of stem, called *thick necks*, do not incline to ripen at all. These latter should be marked for immediate use, and left on the ground till required; or, if the ground is wanted for another crop, they may be taken up and laid in *by the heels* in some out-of-the-way place, till used up. The process of laying by the heels is thus performed: a trench is opened, and the plants, as they are taken up, are set in it pretty thickly, to economise space, but not so thickly as to cause them to rot or sustain injury from want of air. They are placed in a slanting direction against the back of the trench, and covered over as deep as they formerly were in the ground, the earth being laid over their roots and stems in the course of digging the ground to prepare it for another trench, which should be so far apart from the last that the leaves of the plants may not lie over those of the preceding row. The principal object, however, is to check vegetation and prevent the plants running to seed, hence the coldest situations should be chosen. The others should be gone over, and their stems bent gently over, or the strongest of them may have their necks twisted; this will check growth, and tend to their ripening. The sooner they are taken out of the ground after their growth has nearly ceased, the better; for, if left in, they

are often attacked by maggots. As they are taken up, they should be placed in a dry airy place, but not in the full sun, to dry; and it will greatly facilitate that process if, instead of being left lying on the ground, they are spread thinly on boarding laid upon a gravel or paved walk or yard. As they dry, the roughest of the decaying leaves should be removed; and they should then be carried to the root-room or onion-loft, and spread thinly upon the shelves, floor, &c., to dry more completely. From this time until there is danger of frost entering the onion-room, the doors and windows should be kept constantly open, to afford them all the ventilation possible. The remainder may be removed into the house as fast as they dry sufficiently, and all should be at once taken up in the event of frost. After housing, they should be repeatedly examined, all decaying bulbs removed, and the whole frequently turned over.

The future management of the bulbs depends on the exclusion of frost; yet a low temperature must be preserved and ample ventilation given. When time permits, and wet days offer a good opportunity, a general dressing should take place. The smaller bulbs ought to be selected, and kept by themselves, for pickling, and many other uses which no being on earth could think of but a French or Italian cook. The next in size, which will also be the next best maturely ripened, should also be picked out: these are likely to keep longest, and should therefore be kept by themselves on the higher shelves, so as to be better out of the way. Those having a portion of the dried leaves still attached to them had better be strung up, and suspended from the roof part of the room. The process of stringing is thus performed: Three or four onions, having a portion of their tails still attached to them, are taken in one hand, while with the other a strand of matting or twine is to be tied round them. After placing three or four more bulbs, the twine or matting is wound round them pretty tightly—and so on, till the rope or bundle has attained a yard or so in length, when it is suspended by one end to the roof or other convenient part of the root-room. This is a good way of wintering onions, and takes up little space. The imported Portugal onions are secured in nearly the

same manner, only a heated iron is applied to the base of the bulb where the fragments of the roots still exist; burning them off, and very slightly searing the base, tends to destroy vegetable life, and hence prevents the bulbs from sprouting during winter. And as we take some delight in showing that all things are not new under the sun, we may here just by the way mention that Pliny, to secure a similar end, adopted a somewhat similar means, as he recommends those who wish to keep their onions from sprouting to dip their heads in warm salt water.

Approved sorts, and their qualities.—The varieties of cultivated onions have long been, and still are numerous. Of those that are annually produced from seed, the following may be considered the best:—

1. *Brown globe.*—Large, globular, palish brown, slightly tinged with red; a very useful and hardy kind, of mild flavour, and keeps well.

2. *New white globe.*—Rather flatter in form than the last; of mild flavour; altogether a very handsome bulb; comparatively a new variety.

3. *Blood red.*—Known also as *the Dutch* and *St Thomas's* onion, of which there are also two sub-varieties,—viz., *pale* and *very deep blood*: a very old variety, esteemed by some for its extreme pungency, and also for its diuretic quality. Of middle size, flattish, and very hardy; deep red, or blood-coloured, keeps remarkably well; much grown amongst the Scottish and Welsh peasantry. Not greatly appreciated in genteel families. Perhaps one of the oldest cultivated sorts, as we find them noticed for their strong flavour so early as the days of Pliny.

4. *Reading.*—Supposed to be synonymous with (or so closely allied as to be scarce worth growing as distinct varieties) *the Cambridge, white Spanish, Eversham, and white Portugal.* It is much cultivated about Eversham, and also about Reading, and hence the origin of two of the names. An excellent sort for a general crop, but does not keep well; mild, large, flat, of a whitish colour tinged with green.

Strasburg.—Known also as *the Dutch, Essex, Deptford, and Flanders* onion. This is the most generally cultivated variety in Britain. A large oval bulb, reddish, tinged with green; extremely hardy, and hence generally sown for autumnal crops, and should be preferred in all cold and elevated localities: flavour rather pungent, no disqualification to palates *vulgar*, and has also the merit of keeping well.

6. *Tripoli.*—In seed-lists we find a round and a flat variety, both of which may be picked out of the same seed-bed; reddish, tinged with green and brown, soft and mild, does not keep well, but an excellent autumn sort. The largest onion grown.

7. *Silver-skinned.*—Of which there are the following sub-varieties, scarcely distinguishable except in name—viz., *early silver-skinned, small*

silver-skinned, Nooera; flat, middle-sized, and shining when grown in rich ground. It is chiefly cultivated for pickling and dressed dishes, for which purposes it should not much exceed in size a large hazel-nut. It is usually sown in poor soil to prevent it becoming large.

8. *Madeira large.*—Known also as *new giant*: a new variety, the seed of which is annually imported from Madeira; a bulb of extraordinary size, but does not keep well.

9. *True Portugal.*—Large, flattish, globe-shaped, exceedingly mild in flavour, but does not keep well, particularly if grown in Britain, as we have not climate to ripen it thoroughly. Genuine seed should be imported from Portugal. We have some doubts, however, as to this being different from the *brown Portugal* of the seed-shops.

10. *James's keeping.*—Evidently an English hybrid, and said to have originated with a Mr James, a commercial grower of Lambeth Marsh: of large pyramidal shape, brownish coloured, strong in flavour, and one of our best keepers, probably on account of its English origin, and consequent increased hardness.

11. *Lisbon,* known also as *Lisbon white.*—Genuine seed of this excellent variety is in general imported from the south of France. It is by no means hardy with us, and is slow in ripening; not to be recommended for a cold climate; of large size and globular form, skin whitish and very thin. Opinions differ as to the hardness of this variety; it is described as hardy, and adapted for autumnal sowing by several good authorities: we have found it one of the tenderest.

12. *Two-bladed,* known also as *the Welsh onion,* from being much grown in that part of the kingdom.—This has a small, flat, brownish-green bulb, which ripens early, and keeps well. It is grown chiefly for its leaves, which are used in salads, and its small bulbs for pickling. The *two-bladed early* of some seed-catalogues is the same as this, which, by the way, ranks as a distinct species (*Allium fistulosum*, L.), and is a native of Siberia. Introduced in 1629. Some nursery catalogues enumerate a greater number of names, but their difference consists in the name only.

13. *Tree, or bulb-producing onion.*—This is a viviparous variety of the common onion; a native of Canada, the climate of which being too cold to enable the plant to produce seeds, nature employs one of those beautiful provisions she has in store for the fulfilment of the sacred command, "multiply and replenish," by the production of viviparous bulbs at the top of the stalk, which otherwise would have been graced with its head of flowers and umbel of seeds: they are sometimes produced on the sides of the flower-stem also. This occurrence is not uncommon in sub-alpine situations, where the temperature is too low for the ripening of seeds, and is well illustrated in many of the pasture-grasses; the *Festuca vivipara* offering one example, and one of the sub-varieties of the common rye-grass (*Lolium perenne*, var. *vivipara*) another. Why botanists have elevated the former into a species, and the latter not, appears

anomalous. These cauline bulbs are planted in spring, and produce ground-onions of a very useful size; and, although smaller than the ordinary sorts, they make up for size in greater pungency of quality.

14. *Potato, or underground onion.*—For a somewhat similar purpose, this sort, which seldom ripens its seeds, increases itself by the formation of bulbs under the ground, as if determined to be the very antipodes of the last. This variety has been in cultivation just about half a century in the southern parts of England, where, on account of the crop ripening much sooner than that of the seed-produced sorts, a ready market has long been found for them in supplying ships leaving our ports in June and July, at which season they could not procure others fit for keeping. It has been stated to have been brought to this country from Egypt by our troops, on their return, after driving the French out of that country, about the beginning of the present century; and of this we entertain not a shadow of doubt, the land of Egypt being the land of onions since the days of the Pharaohs at least. This variety is cultivated to a very great extent in that country, and its singular mode of growth, apart from its excellent qualities, would no doubt attract the attention of our soldiers, who could hardly be supposed to be aware of the fact that it had been grown to a limited extent a few years only prior to the time to which we allude, in a London nursery. This onion is well adapted for cottage gardens, even in climates where the ordinary sorts do not ripen. It is cultivated to very great perfection in the parish of Currie, west of Edinburgh, where we have seen them as large and fine as in Devonshire. The mode of cultivation differs not from that of the shallot and garlic already disposed of, except that the individual bulbs do not admit of division; but in taking up the crop, numerous small bulbs will be found clustered among the larger ones, which are all attached to the main root after the manner of potatoes, and hence its trivial name of potato-onion. The plants growing stronger than either shallots or garlic, require more space both between the rows and also between each other in the line. Fifteen inches by ten may be given as an average distance. In one particular more they essentially differ; their bulbs are formed under ground: therefore, although the planted bulbs are best set on the surface, the earth should be gathered up around them in the way recommended (but with doubtful advantage) in the case of the potato. Their subsequent culture consists in keeping them clear of weeds, and a liberal supply of liquid manure during warm weather only. Planting should be attended to in November, although, in cold places, March may be with some advantage chosen. By the end of June, or beginning of July, they are fit, in most places, for taking up. Their curing and keeping are the same as we have already described for the others of the tribe. Much of the success, however, depends on the state of the ground. This is a root which we hold to be of importance in every garden, though it is too seldom found. In Devonshire, where they are

much grown, there is a familiar saying, "Plant on the shortest day, and take up on the longest." This onion, like all the tribe of cultivated alliaceous plants, requires a rich deep soil, well manured, and dry at bottom. For this purpose the ground should be deeply trenched, and the manure (pigeons' dung, or the offal of a slaughter-house, if they can be obtained), wrought in during the process; for, although it is perhaps not generally known, the roots of this variety have been found extending to the depth of six feet under the surface. When the soil is naturally shallow, it should be gathered up in ridges, and upon these the sets should be planted. For cold situations, this has another advantage, as the solar rays will penetrate such ridges, and impart a greater degree of warmth to the soil around the roots than if they were planted on a flat surface. In establishments where fully ripened onions are required throughout the year, these may be brought forward at even a sufficiently early period to succeed the ordinary kinds that have been preserved during the winter. To effect this, the bulbs should be planted in pots in October or November, and kept in a cool pit through the winter, and turned carefully out into a well-prepared border at the bottom of a south wall (or equally warm place) early in March. The autumn-planted crop will require to be looked at during winter, and any bulbs that may have been thrown out, or displaced by the frost, reset; and in the coldest of all localities, a little mulching or rotten dung or leaves may, with advantage, be placed on the surface between the rows. This will exclude frost and the drought of spring at the same time.

The *Welsh onion, or Ciboule*, is seldom grown. It is an extremely hardy perennial of strong flavour, but does not produce bulbs. It is sown in August, to be drawn green in spring, for use in the manner of leeks, and in that state is not unfrequently termed scallion—an epithet applied by country people to all sorts of onions when they do not produce bulbs.

Onions for pickling are in demand in every family. For this purpose the silver-skinned varieties should be chosen, on account of their delicate white colour, slightly intermixed with greenish lines between the coatings. As they are usually preferred when small—about the size of a filbert—it is necessary they be sown on very poor soil. We have a border, the soil of which is soft alluvial sand: on this we have grown silver-skinned onions annually during the last thirteen years; trenching it as soon as the crop is gathered, two feet in depth, giving it no manure whatever; sowing thickly in the broadcast manner, in three feet beds—which are formed after the crop has come above ground, by running a hoe from side to side, and thus forming alleys fifteen inches broad, the seed having, to save time, been sown all over the piece. The situation is warm, which insures the ripening of the bulbs; the soil being very poor, and the crop thick, produces them of a small uniform size. In small gardens, and in those wherein the soil is of a very rich nature, such onions are difficult to procure. Sowing

under the shade of trees has been recommended, but not judiciously. As a bed ten feet by four would produce a sufficient quantity for a small family, it were better to prepare such a space artificially, by removing the rich soil to the depth of eighteen inches, and replacing it with poor sandy or gravelly soil. We have grown pickling onions upon a bed of loamy gravel laid on the surface of the ordinary soil, to the thickness of twelve inches.

Diseases and insects.—The diseases and insects to which the cultivated alliaceous plants are liable, if not numerous, are sufficiently destructive. One of our greatest pests is

The common onion-fly (*Anthomyia ceparum*, Bouché). It is thus described by Mr Curtis, one of our highest entomological authorities, in the "Gardeners' Chronicle," 1841:—"The male is of an ashy colour, roughish, with black bristles and hairs; the eyes are contiguous and reddish; the face silvery white; horns black; there are three obscure lines down the trunk, and a line of long blackish spots down the centre of the body, more or less visible in different lights; the wings are transparent, slightly iridescent, tinged with ochre at the base; the nervures pale brown; poisers ochreous; legs ashy brown. The female is ochreous, or ashy grey, clothed with black bristles and hairs; the eyes are reddish and remote, with a light chestnut stripe between them, bifid and darkest at the base; face yellowish white."

This insect attacks the plants in their young state, and continues feeding on them during the whole summer. Sometimes they attack the crop generally, and cause a total failure; at other times attacking them in patches only, the effects being most observable in dry weather—the leaves turning yellowish, becoming flaccid, and the plant at last falling over and decaying. On removing the outer coating or skin of the plants destroyed, the cause will be discovered in the presence of a small grub, which eats its way into the very heart of the onion. This grub is white, smooth, and shining, and of a conical form, and nearly half an inch long. The eggs are deposited on the leaves when in a very young state, and close to the earth; as soon as the maggots are hatched, which takes place about the time the plants are about the size of a small quill, they bore their way through the outer leaf, and penetrate the onion at its base,

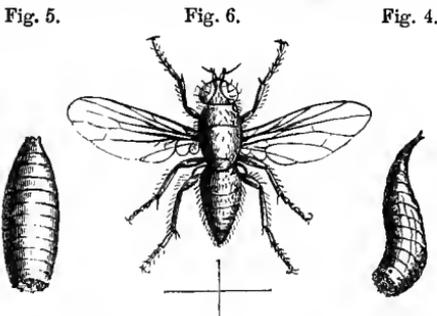

feeding chiefly on the bottom part of the bulb, causing it to separate from the roots, and occasioning a mass of mouldiness, familiar to every cultivator. These grubs, in general, attain their full size in about fourteen days, sooner in dry weather than in wet, and at that period descend into the earth, to undergo their transformations, when they become a reddish brown, indurated pupa, of an oval form. Fig. 4 shows the grub; fig. 5, the pupa; and fig. 6, the perfect insect.

Another enemy has recently appeared in the brassy onion-fly (*Eumerus cneus*). This fly was discovered by Mr Curtis in 1842, and figured and described by him in the "Gardeners' Chronicle" for that year, (p. 252.) He detected the maggots in a box containing some rotten onions, which he found to be distinct from *Anthomyia ceparum*, the common onion-fly. "It is densely clothed with short hairs, thickly and distinctly punctured, and of an olive green, with brassy tinge; the antennæ are entirely black, the seta naked; the face is very hairy, simply convex, and silvery white; eyes dark-brown and slightly pubescent; rostrum very short; thorax with two whitish lines down the back; scutel semiorbicular, the margin thin, and somewhat denticulated and ciliated; abdomen linear in the males, the segments cœcate or constricted at the base—attenuated to the apex in the female, with six grey lunulate marks, three on each side, and nearly meeting on the back; wings transparent; the nervures piceous, the apical transverse, one somewhat bilobed; poisers yellowish white; legs rather short and stout, especially the hinder, the thighs being incrossated and serrated beneath with a double row of minute teeth; tibiæ bright rust colour at the base, the hinder curved; tarsi five-jointed and black, the hinder orange colour on the inside; the claws are small, and the suckers bilobed."

Specimens of this fly have been taken in the neighbourhood of London, flying about in June and July. The female has not as yet been observed depositing her eggs. The maggots do not confine themselves to the onion alone, but have been observed on cabbage-roots.

These may be considered the chief enemies to the onion tribe, attacking them all indiscriminately—the garlic, however, less than the others. The latter does not as yet appear to have spread, so as to be of the same importance as the former. The means hitherto employed for subduing these insects are these: Laying soot over the beds, or incorporating it with the soil; applying salt in the same manner; watering with lime-water, gas-tar, stale soap-suds, soot-water, stale urine, old tobacco-water, &c. It is evident, however, that it is not the smell which affects them—for few things can be more offensive than rotten onions, on which both these insects appear to luxuriate.

Their power of reproduction is so great, that unless they are destroyed the moment they are discovered to have attacked the crop (which will readily be known by the leaves drooping and turning yellow), their total eradication becomes next to impossible. All other means (except carefully pulling up every diseased

THE ONION-FLY, GRUB, AND PUPA.

plant, and committing them to the fire, collecting the soil around where they have been growing, and burning it also) can only be regarded as exceedingly superficial in their effects. Deep trenching and frequently turning over the soil are of great advantage: in the one case burying the pupa too deep for its again reaching the surface; and in the other, disturbing it during its transformation, and probably preventing that change from taking place. From what has been shown above of the economy of the onion-fly, it is clear that the most rational method of eradicating it is to capture the insects while in the grub state, and while they are entrapped within the onion. By doing so, their increase is greatly diminished; as it is probable that, for every grub so destroyed, hundreds of flies are prevented from appearing in spring, each of which may be the parent of hundreds of grubs during the following season. All other proposed remedies may be set down as comparatively worthless. Sowing onions year after year on the same ground is a very certain way of multiplying these insects, and might be carried to the extent of literally stocking the ground with them. Insects peculiar to any plant seldom attack the crop during the first year, and probably the second, after being planted in land not previously occupied with the same kind of crop, because the soil has not as yet become furnished with the pupæ of the insect peculiar to the plant. Hence some advantage arises from sowing onions after celery, and *vice versâ*, cabbage after potatoes, &c. Spirits of tar is of great use, if applied in sufficient quantity to the soil immediately after the crop is removed; and it is a good plan to run it along (from the spout of a watering-pot) the lines of the rows where the onions had grown, because in that way, and at that exact time, it reaches the pupa in its most tender state; not, however, that it acts as an ordinary poison (the pupa not being in a feeding state), but it penetrates through the skin whenever it comes in contact with it; and no insect, in any of its stages, out of hundreds we have submitted to the ordeal, will exist after being brought into contact with this liquid. It is probable, also, that many other applications (turpentine, for example), if applied at this time, and in this way, might be found exceedingly efficacious.

Soot is not only an excellent manure for onions, but is also a safe precaution against the attacks of the grub. It may be sown broadcast all over the ground, previous to drilling, if in abundance; if scarce, sow it in the drills when formed. The following has been often applied to onion crops, even after the attack has commenced: Water the ground well (that is, give it a good soaking of water) in the following proportions,—add to 20 gallons of rain-water 1 peck of unslaked lime, $\frac{1}{2}$ peck of soot that has not been exposed to wet, 2 gallons of urine, 1 lb. of soft soap, and 2 lb. of flowers of sulphur; when the mixture is sufficiently settled to pass through the rose of a watering-pot, it may be applied. As a preventive of the grub in onions, it has been recommended to sow them on

ground previously cropped with turnip. If advantage arise from this, it is founded on the rotation system.

The chemical action of soot, in this and in similar cases, as a fertiliser and preventive of grub, may depend on the elements of which it is constituted, which are carbonaceous matter, mixed with carbonated ammonia, giving out a strong pungent smell by the action of quicklime. It affords a brown extractive matter of a bitter taste, some ammoniacal salts, and an empyreumatic oil, either or all of which are disagreeable, if not really fatal, to insect life. Its chief basis, however, is charcoal in a state capable of being rendered soluble by the action of oxygen and water. Powdered charcoal has been found exceedingly efficacious in preserving the onion crop, but not to the same extent as soot, containing in itself few of the elements of which soot is composed. We were led to apply soot in a liquid form, as M. Branconnet has shown that "a watery infusion of soot is eminently antiseptic, and may be used for preserving animal matter from decomposition;" and antiseptics we find in practice greatly to preserve the parts of plants, to which they are applied, from rotteness, to which the onion is extremely liable when attacked by the grub.

The variety of silver-skinned onion known as Oignon de Nocera is sometimes attacked by a minute parasitic fungus (*Vermicularia circinans*). It appears in form of small round black spots, which, although not penetrating the substance of the bulb, greatly disfigure it, and render it unfit for use. This disease appears to be quite new, and was first detected in the gardens of the Horticultural Society of London in 1851.

Saving of seed, &c.—The saving of onion seed is carried on to a very great extent in the neighbourhood of Reading, in various parts of Kent, to some extent in Cambridgeshire, Bedfordshire, and about Evesham. The great supply, however, is imported from France and Holland. The saving of any esculent vegetable seed, while it can be purchased genuine from the regular seedsmen, is the reverse of economy. Amateurs, however, often save various sorts of seed, as much for the satisfaction of presenting them to their friends, as on the mere score of economy to themselves. Gardeners are not unfrequently driven to this, as an expedient to preserve any particularly fine variety they may become possessed of, as well as to guard themselves against fraudulent dealers, who, it is to be regretted, are on the increase. There is no economy, however, in saving seeds with a view to evade paying a yearly seed-bill. Seeds so produced cost 100 per cent more than they can be purchased for. They are

seldom so good, can never be calculated upon as pure, if more than one species be grown in the same garden, or indeed within a very considerable distance around.—For reasons, *vide* art. PROPAGATION BY SEED.

To save onion seed, select some of the largest, best formed, and best ripened bulbs; prepare the ground as already directed, only choosing the warmest and most sheltered spot the garden affords—for climate is the principal reason why we are compelled to import seed, which, until these few years, was subjected to an import duty almost equal to the prime cost. In November plant them, as we have advised for garlic and shallots. As the shoots advance in height, a line of stakes, three feet in height above the surface, should be driven in along each line of plants, and to these a double course of packthread or tarred cord should be fastened, by taking a turn of the cord around each stake, thus leaving the stems of the plants to grow up between the cords for their support; and, for greater security, these cords should be tied together at every twelve or fifteen inches in length. As the flower stems extend in height, add other courses of cord, till the height of nearly three feet is attained, at which height the heads of flowers will appear, and, if not broken by the wind, will become large heads of seed, which will ripen in August or September. The stems should be cut over then, and laid down for a day or two to dry; afterwards they may be tied up in bundles, further dried in the sun, and ultimately, if the crop is large, stacked by till thrashed out, or suspended in bundles from the roof, in a dry airy apartment, and rubbed out and winnowed at convenience. One ounce of seed contains 7636 seeds.

The European names of the onion are, Oignon in French; Zwiebel in German; Uijon in Dutch; Cipolla in Italian; Cebolla in Spanish.

§ 5.—THE LEEK.

Natural history.—The Leek, *Allium porrum*, L. (from Celtic, *Pori*, to eat), belongs to the same natural order, and ranks in the same class and order in the Linnæan arrangement as the four last. It is said to be a native of Switzer-

land; of this there are as great doubts as that the onion is a native of Spain. It is undoubtedly a native of the East, and was cultivated largely in Egypt in the days of the Pharaohs. Phillips, in "History of Culinary Vegetables," vol. ii. p. 30, has thrown more light upon this dark subject than any other author we have read. He says, in speaking of this plant being adopted by the ancient Welsh as their badge, "The Welshmen still continue to wear leeks on St David's Day, in commemoration of a victory which they obtained over the Saxons in the sixth century, and which they attributed to the leeks they wore, by the order of St David, to distinguish them in the battle. The Welsh patron died about the year 544." Now, they must have been not only introduced, but much cultivated at this early period. That the leek is a native of Egypt is evident; for, besides the notice taken of it in the Bible, Pliny, in book xix. chap. 6, states "that the best leeks were brought from Egypt, and the next to them from Orthes, a town of Asia Minor," now called Guzelhizar. Aricia in Italy was celebrated for leeks in Pliny's time; for he says, "It is not long since leeks were brought into great notice through the Emperor Nero." Tusser sings their praise in verse, and says they were in common use in farm-houses long before his time. And Gerard, writing soon after Tusser's time, speaks of leeks in such a manner as to induce us to think them indigenous to our soil.

Its date of introduction is given in "Hortus Britannicus" as 1562. In this case, as in several others in that work, when the date of a plant is not exactly known, the first year in which it is known to have existed in Britain, upon published authority, is given. That it was to some extent cultivated prior to that year is evident from the familiar way in which all our oldest gardening authors speak of it, and it is noticed by most of them.

Uses.—This plant has been more generally used as an esculent in Wales and Scotland than in England. It is now, however, cultivated much more generally in the gardens of the latter, and brought in greater quantities to their markets than formerly. The whole plant, except the roots, is used in soups and stews. The white stems, which are blanched by being planted deep for the purpose, are now largely used, boiled and served up with toasted bread and white sauce, and eaten like asparagus. They are much used in French cookery, and form an important ingredient in Scotch winter broth, particularly that national dish *cock-a-leekie*. But the most extraordinary use to which we have heard of their being applied is thus stated on the authority of no less a person than Lord Bacon, who says (in "Essay on Gardens," century ten), "I knew a gentleman that would fast (sometimes) three or four, yea, five days, without meat, bread, or drink; but the same man used to have continually a wisp of herbs that he smelt on, and amongst these herbs some of strong scent, as onions, garlic, leeks, and the like." The leek is a valuable vegetable for the cottager, a small piece of ground affording him a large and useful supply during winter and spring, when green

food is scarce. It is easily cultivated and extremely hardy. The medicinal and dietary properties of the leek are similar to those of the onion, only in a milder degree.

Mode of propagation.—Leeks are propagated by seed sown for ordinary purposes at the same time as onions. Bulk of plant, in the case of the leek, being a primary object—and transplanting tends greatly to insure this—the seed is sown pretty thickly on a bed, and when of sufficient size, the plants are removed to where they are to come to perfection. Those who have not the convenience of a hotbed should sow the seed early in February, in as warm a spot as is at their disposal. Where, however, it is wished to have the leek in its fullest perfection, the seed should be sown thinly on a mild hotbed, such as of leaves in a state of fermentation, a material within the reach of most; while those near a tanyard may employ bark, or those in the vicinity of flax-mills the refuse flax—either of which, put up in the form of a cucumber-bed, will afford a mild and lasting heat. Without a glass frame, the purpose may be served by an occasional covering of tarpauling during frosty nights or heavy rains. Slight excitement only is required. The seed should be sown of a uniform thickness on rich compost, and covered to about the depth of a quarter of an inch, half an ounce being sufficient for a bed 2 feet by 4, and so in like proportion for beds of larger size. Keep them clear of weeds, and water with tepid water occasionally until fit for transplanting. One ounce of seed contains 2924.

Sowing and planting.—Sowing in the open ground may be performed from the beginning of February till the middle of April, the exact time depending entirely on the state of the weather and the condition of the soil. The earlier, however, the seed is sown the better, that the plants may attain a good size before final transplanting. If sown in beds of 4 feet in breadth, and in the broadcast manner, the same process should be followed as recommended for onions grown in that way. If sown as advised above, and which is much the best way, as soon as the young plants are of the height of 3 inches they should be carefully taken up, loosening the soil in the bed so that none of the fibres may be in the least injured. They

should then be transplanted into another preparatory bed, having the same advantages of heat, &c., as the first; but on this the heating material should be covered with completely rotten manure to the depth of 4 inches, and the plants set in it at the distance of 3 inches apart each way. This is to encourage their growth. When they have attained the height of 6 inches, another bed of equally rotten manure should be prepared for them, placed on the surface of the ground in a warm sheltered spot, but without bottom heat, and the plants a second time removed, with all their fibres entire, and planted in it at the distance of 6 inches apart each way; for here they are to remain till the season of final transplanting arrives, which will be from the beginning to the middle or end of May. The plants, having thus plenty of room, will attain the size of 9 inches or a foot, and be of goodly size of stem, which will be promoted by frequently watering them with liquid manure. Few people pay this attention to them, but transplant them at once from the seed-bed to where they are to grow to full size. In this they lose much, both in the size and delicacy of the produce, as the more rapidly all esculent plants are grown, the more tender they are. The ground being prepared for them, they are to be set in lines 18 inches apart, and the plants 10 inches from each other in the line—that is, if the largest size be wished for; otherwise, 12 inches by 7 will be sufficient. In planting, the dibber used should be $3\frac{1}{2}$ inches in diameter, obtuse at the point; but, if nearly cylindrical in form, so much the better, that the roots may have room in the bottom of the hole. The plants being taken carefully up, with as much of the rotten manure attached to them as possible, and carried to the spot on a shallow wooden tray, they are to be dropped carefully into each hole as it is made, and no soil whatever placed over them, as the rains and occasional waterings—probably one at the time of planting—will wash down sufficient to cover the roots to the extent required. The object of this large hole is, to allow the stem to swell out in size, without being compressed by the surrounding soil. The dibber should have a cross piece of wood fastened to it, form-

ing a gauge as to the equality of the depth of each hole. The old and barbarous system long recorded in books, and practised by even the best gardeners, of cutting off a portion of the tops of the leaves, should be disregarded; and the curtailments of the roots, long held as a beneficial process, should be looked upon as an act of wanton madness. This is the usual mode of planting. A much better way is to stretch the line from end to end of the field, and, with a spade, to take out a trench a foot at least in depth, leaving the back of the trench immediately under the line as nearly perpendicular as possible. Along this trench set the plants, resting against the solid ground, placing their roots with the ball of manure around them in the bottom, and filling in the earth taken out of the trench carefully around them—taking care, however, not to let it reach so high as to cover the hearts of the plants. Water at the time of planting, if the soil be not already too damp, in which state it would be better to delay planting till it dry. However, by this drill mode of planting this crop, as well as most others, the ground is left quite open and loose, as the operator is always standing on the ground that is to be loosened up in the formation of the next drill. One sowing is, in general, sufficient for private families in Scotland; but in the south, where vegetation is so much more rapid, a second, or even a third sowing, may be found of advantage for continuing the crop till late in spring. Our own practice is to sow once, and, in the beginning of March, to dig up the crop, and lay it over in a cool shady place, covering the stems as high as they are blanched—a plan we have found much more suitable than that of sowing on heat for the early and main crop, and afterwards in April or May for late crops. Indeed, we have frequently found those sown in May run to seed at the very time those sown in February did. The only inducement for making successional sowings is, that some French cooks require them of a small size; and, to meet such demands, successional sowings should be made from February till July. Some plant in open trenches, after the manner of celery, and earth the plants as they proceed.

Subsequent cultivation.—The subsequent

management consists in drawing a little earth to the stems as they elongate, keeping the ground clear of weeds, repeatedly stirring the surface between the rows, and of all things avoiding the practice of cropping the leaves—an old and nearly obsolete mode—which, however, has been recently recommended, with a view, it is asserted, of increasing the size of the stems.

Soil and Manures.—The soil, from what we have already stated, cannot be over rich, nor, indeed, need the manure be at all so decomposed as for onions. We believe the leek would luxuriate well on the top of a dunghill. It is important, however, that the ground be deeply trenched, and also that the manure be nearly as deeply buried; for as the roots are from one to two feet or more under the surface, so also should the manure be. Deep alluvial soils, if dry at bottom, are excellent for the leek; and next, those that are of a deep rich loamy nature: light shallow ones are the worst of all. In these latter, the plants should be set on the surface upon a bed of rich manure, and earthed up as they proceed, as is practised with celery.

Forcing.—The leek is never forced beyond the slight extent noticed above, to forward them for final planting.

Taking the crop, and subsequent preservation.—The crop is left in the ground till wanted for use. It is expedient, however, upon the appearance of frost, to take up a quantity to be laid in soil or sand in the root cellar, or other place of shelter, so as to be conveniently got at when wanted for use.

Approved sorts and their qualities.—The seed-lists contain several names of sorts: of these, the Large Flag, London Flag, English Flag may be considered as identical. The Musselburgh is an early improvement on the Scotch Flag; and what is now called the Edinburgh Improved, appears to be only selected from the Musselburgh stock. The Dutch Flag, Erfurt, and Rouen, seem, as they are at present growing in alternate rows in the Dalkeith gardens, to be in no-wise different from each other. They appear, however, to be disposed to attain a greater growth than any of the others. There is a sort of Allium grown in Pembrokeshire, and along the Welsh borders, called the hollow leek, producing roots in clusters like shallots. It is, however, scarcely worth the notice of the modern horticulturist, in the presence of so many sorts that are superior.

Saving of seed.—In saving seed, some of

the largest and finest specimens should be selected; and as we in the North have scarcely climate for saving this or the onion, it has been found expedient to plant them at the bottom of a south wall, and to support the flower stems by it. In such a way, considerable quantities of good seed are annually produced about Musselburgh, and in other warm localities. In better climates, the same mode is followed as recommended for onions, (*which see*.)

The European names are—Porreau, or Ail à tuniques, in French; zahme Lauch, gemeiner Lauch, Porro-Zwiebel, or Spanische Lauch, in German; Porro, or Porreta, in Italian; Puerro in Spanish; Alho Porro in Portuguese; Purio in Swedish; Pras in Russian; Prei, Look, or Porreye, in Dutch.

§ 6.—THE CHIVE.

Natural history.—The chive (*Allium Schoenoprasum*, L.) belongs to the same natural order, and ranks in the same class and order in the Linnæan arrangement as the five last. It is indigenous to various parts of Britain, occasionally found in meadows and pastures, but at no great elevation.

Uses.—The young leaves are the parts used; the roots, although bulbs, are very small, and although partaking of the taste and properties of the rest of the family, have never, so far as we are aware of, been used as an article of food. The young leaves are used in mixed salads as a substitute for young onions, and by many are preferred, being milder in flavour. They are used in a young tender state; and, to keep up a succession during spring, summer, and autumn, the plants are repeatedly cut over, whether the leaves are required or not, the intention being to have them always young. During winter they are obtained from plants taken up in autumn, and potted and kept in a mild temperature, say from 45 to 55. They are very much used in soups, particularly in Scotch families, for seasoning various dishes,

shred in small pieces, and served up with beef-steaks, being sprinkled over them just as they are taken from the fire. They are next to indispensable in omelets, and hence are much more used on the Continent, particularly in Roman Catholic countries, than in Britain. The process of gathering them is to cut them over near the ground, but so as to carry no earthy matter with them, for as much of their flavour would be lost by washing. They are then tied up in small bunches, ready for the kitchen. The circumstance of their being gathered in this way, Loudon remarks, has caused them to be spoken of in the plural, *Chives*.

Mode of propagation, cultivation, &c.—They are propagated by division of the roots either in the spring or autumn. Their roots, growing in bundles, admit of this mode with great facility. They may also be singled out and planted individually, but this is seldom done. They grow in bunches often 6 or 8 inches in diameter. One of these may be divided into a dozen or more pieces, each of which will, in a few weeks, if planted in spring, form a compact patch. Each patch should stand clear of the other, so that in forming a new bed of them, they should be set a foot or 15 inches asunder. A plantation will last for many years, but it is well to renew them every third or fourth year. All the cultivation they require is to be kept clear of weeds, and the leaves frequently cut over. They will prosper in any ordinary garden ground, and there is only one variety in cultivation.

The European names are—Ciboulette, or Civette, in French; der Binsenlauch, or Schnittlauch, in German; Bieslook, or Suyprei, in Dutch; Cipoletta maligia in Italian; Cibollino de Inglaterra in Spanish; Cebolinha de Ingalaterra in Portuguese; Graslog in Danish; Luczer-lupny in Polish.

CHAPTER II.

LEGUMINOUS PLANTS, OR THE PULSE TRIBE.

As has been elsewhere stated, plants of this natural order are recorded to have been amongst the first vegetables employed by man as articles of food. The legumes or pods, either in their earlier stages of growth, as in the case of the kidney bean, or in their more advanced growth, as the pea and bean, the seeds of which are eaten both in a green and ripened form, are the parts of the plant employed in culinary matters. This very extensive order contains no less than 244 genera, and upwards of 2630 species. Of these, the following, with their sub-varieties, hold a prominent position in garden culture, viz. :—The Pea, Garden Bean, Kidney, French or Haricot Bean.

§ 1.—THE PEA.

Natural history.—The pea (*Pisum sativum*, L.) belongs to the natural order Leguminosæ, subdivision Sarcobolæ; tribe Vicieæ; and to the class Diadelphia, and order Decandria, in the Linnæan arrangement. The genus *Pisum* contains seven species; three of which are cultivated for culinary purposes, besides the varieties and sub-varieties of *Pisum sativum*, whose name is legion—if faith is to be placed in the list of names found in seedsmen's catalogues. *Pisum maritimum*, a species which is indigenous to some parts of the east coast of England, has in former times been used as an article of food in times of scarcity. The name *Pisum* is derived from the Celtic *pis*, a pea; or, according to Philips, from Pisa (a town of Elis), where peae anciently grew in great plenty. The English name appears to be a corruption of the Latin. Tusser, who wrote in the time of Queen Mary, and Gerard, soon after him, both wrote it "Peason;" Dr Holland, writing in the time of Charles I., spells it Pease, since abbreviated into Pea.

The native country of the pea, like that of most of our cultivated esculents, is not now known. Modern catalogues refer it to the south

of France, and Valmont Bomare distinctly says, "the garden pea was originally from France;" and Mr Coles, in his History of Plants, says the Fulham pea, which came first out of Fulham, is so called because the grounds about Fulham, "neere London, doe bring them forward soonest." Pease undoubtedly came originally into France, Italy, and Spain, from the East; and although we cannot identify the lentils used in the days of Jacob and Esau with the pea of later times, still, we know they were cultivated by both the Greeks and Romans in the time of Pliny, who informs us that the former sowed their pea in November, but the latter did not plant theirs till spring—and then only in warm places lying well to the sun. "For," says he, "of all things, pea cannot endure cold."

The time of their introduction into Britain is as uncertain as their native place. That they were cultivated to some extent in the time of Henry VIII. is more than probable, as one variety, the Rouncival—a name continued down to the present day—is mentioned by Tusser, in his "Five Hundred Points of Good Husbandry," who says,—

"Dig garden, 'stroy mallow, now may you at ease,
And set (as a daintie) thy runcival pea!"

And that they were then grown much as at present, would appear from the following line:—

"Stike plenty of bowes among runcival pea,
To clamber thereon, and brach at their ease."

In the early part of Good Queen Bess's reign, they were, however, less abundant than the above quotation would lead us to suppose. For, as Fuller remarks, they were seldom seen, except those brought from Holland, and "these were dainties for ladies—they came so far, and cost so dear."

Green pea appear to have been unknown to our Saxon ancestors; nor was it until after the Norman Conquest, and the establishment of monastic communities, that we read of such being used. Fosbrooke, in "Brit. Monasticon," says that, amongst other rarities, green pea were provided against midsummer, for the nunnery at Barking in Essex. And in "Archæologia," 13, 373, early pea are thus directed to be treated: "If one will have *pease* soone in the year following, such pea are to be sown in the wane of the moon, at St Andrew's tide

before Christmas." Bonnefonds, in his "Jardnier Français," (1651), describes the skinless pea as the Dutch pea, and remarks, that until lately they were exceedingly rare. They appear to have been introduced into France from Holland about 1600. Green pease became a popular delicacy in England soon after the Restoration of Charles II.; and, strange enough, even for late ones so early as 1769, as it is a matter of history that on the 28th October of that year, a guinea a pottle—not quite half a dish—was given in Covent-Garden market; and as much as ten times that sum has been paid since in the same market, for a quart of green pease shelled.

Use.—Pease in their dried state are used in soups, either whole or split; in the latter form they are generally preferred. They are also made into puddings, and occasionally ground into meal: in either way they form an agreeable and nourishing food—not, however, well-suited to those of weak digestion. Old pease are often difficult to boil; indeed, sometimes no boiling will render them soft. This has been said to ensue when they have been kept more than one year; and also that those grown on land which has been manured with lime, marl, or gypsum, will even not boil at all, whatever their age may be. That such a circumstance sometimes occurs as their not boiling, is pretty well known to dealers; but that either of the causes assigned is the true one, seems to us to be doubtful. All the varieties of garden pea are esteemed for their seed while in a young state; indeed, for the tables of the great, they can hardly be either too small or too young. In their second state or size, they are used for greew-pea soup; and, in their third state, when fully grown, but still quite green and soft, they form an ingredient in hodge-podge. In gathering, the young gardener should be informed for which of these purposes they are intended; for whether for the one or the other, the pease should be of a uniform size and age. We may here also observe, that several of our largest-growing varieties are objected to merely on account of size, and therefore it is unwise to indulge exclusively in such sorts; for although excellent, and most profitable to those who wish a good comfortable family dish of duck and green pease, they would be considered unfit for a first-rate table. The marrow-fats, although much prized by some on account of their peculiar fine flavour and delicacy, must give way, in this respect, to Sutton's early champion, Beck's morning star, early Frame, Prince Albert, Auvergne, and such like smaller sorts; while Bishop's new long-podded, Thurstone's reliance, Hair's dwarf mammoth—all first-class pease for profitable culture—must not be calculated upon to afford a supply for mouths genteel. In a sanitary point of view, pease cannot be eaten too young, nor too soon after they are gathered; and hence people who have to depend on the public markets for their supply, seldom taste this very popular vegetable in perfection, and too often have it only when it is almost unfit for use. This is a formidable objection to imported pease. It is, of course, for the interest of the producer to keep back his

pease till they are fully grown, because they measure better, and we believe with many take better, as they get greater bulk for their money. This may be so far excusable on the part of such; but it is inexcusable that a gentleman, having a private garden of his own, should be served with pease otherwise than in the very highest state of perfection—which they are not, if allowed to become too old, or even too large. Mint is usually boiled with pease. It improves the flavour of them while young, and very much enhances the flavour of pea-soup; it also corrects flatulency. A few sprigs of mint should accompany the pease to the kitchen.

There is one section of garden pease called sugar-pease, the pods of which have the inner film wanting, or much less tough than usual. The pods in this section are used with the young seed within them, and are cooked and eaten the same as French or kidney beans. This is a mode of using pease we would like to see much more generally in use: dressed in this way, they afford a delicious and economical dish.

Regarding the nutritive properties of the pea in a green state, we have never met with a satisfactory analysis. In a ripened state, the flour of pease is as three to two of bulk in grain; and when dressed and split for soups, as four to two. According to Sir H. Davy, 1000 parts of pea-flour afforded 574 parts of nutritive or soluble matter; viz., 501 of mucilage, 22 of sugar, 35 of gluten, and 16 of extract, or matter rendered insoluble during the operation. The sugar-pease are much more used on the Continent than with us. The dwarf crooked sugar-pea (pois sans parchemin ou mange tout—zwerger zuckerchoutte), and the tall crooked sugar-pea (pois sans parchemin à grandes cosses—grosse schottige zuckererbse), are met with at every *table d'hôte*.

Yet how seldom do we see such a dish in our own country. This may be looked upon as the more singular, as Gerard, writing in 1597, in speaking of the different sorts of pease, or "peason," as he has it, says there are "some with tough skins, or membrances in the cods; and others have not at all, whose cods are to be eaten with the pease when they be young, as those of the young kidney-beane:" than this nothing can be clearer. Hoffman and Simon Paull treat largely on their medical properties; and Lemery, "On Foods," remarks that "pease contain a viscus and thick juice, which causes flatulency, and produces gross humours; and therefore they are not good for those that are troubled with gravel." Green pease may be preserved for winter use if dried in a cool oven, and afterwards placed in paper bags suspended from the roof in a dry room.

Propagation.—All the cultivated pease, being annuals, are propagated by seed.

Sowing.—The earliest crops to be produced in the open garden, without artificial aid, are obtained by a judicious selection of the most approved early varieties, choosing a favourable soil and situation, and committing the seed to the ground in

the end of October, and throughout November, December, and January. It is of importance, also, in making this selection, that the harder varieties should be chosen. Hamilton's November prolific is one of these. We have seen it, during the two last winters, standing in an elevated part of Dumfriesshire, when other early sorts alongside of it were much injured by the cold. In practice, we find it is not always the crop first sown, however, that is first fit for gathering, even within a few feet of the same altitude, and a quarter of a mile of the same line of latitude. Local circumstances, to a very great extent, set aside in such matters the dicta laid down by those who found the ripening of fruits or of garden crops upon what has been called the geographical distribution of plants. The London market-gardeners, to whom early pease are a remunerating crop, sow in December in rows, in borders under walls, or by the sides of hedges three feet and a half apart. The pease are never staked, and the sorts preferred are, early Frame, Bishop's new long-podded, Groom's superb dwarf blue. Mr Baker, in "Gardeners' Chronicle," 1848, p. 365, on this matter observes:—"I generally sow in November, by a wall in the garden, and the pease are trained to sticks in the usual way; but I have almost invariably picked first from the field crop, although not sown until February. It is very true that, having a large space to collect the first picking from, I gather a pod only here and there; but having found the earliest and best-filled pods nearest the ground, leads me to suppose that, by training on sticks, the exposure to the atmospheric air during night retards the growth, inasmuch as the heat given out by the earth during that period is prevented from assisting the growth of the pea by training them above the ground; and, from the habit of the pea entirely covering the surface, but little circulation of the air takes place among them in the field. My land is a dry, siliceous, and strong soil, and radiates a considerable degree of heat during the day, which also tends to the early production of the crop."

Pease, like all other crops grown in rows or drills, wherever natural obstructions do not occur to prevent it, should be sown in a direction from south to

north, unless in the case of very early crops transplanted at the bottom of a south wall, when, for obvious reasons, the direction should be reversed. The main intention of placing crops in the former direction is, that the sun may have free access to every part of the ground between the lines, and the plants themselves be placed in the most favourable position in this respect also. If placed in a counter direction—namely, from east to west—one side only would have the full advantage of the sun, while the other would derive little advantage whatever. Some draw their lines obliquely, fancying thereby to secure the early morning and late afternoon sun in its greatest vigour, and calculating, also, that its influence is thus more equally diffused. In this, to a certain extent, they are right; but do they who follow this practice truly calculate the angle at which they place their rows, or do they reconcile the angle to the latitude of the place? or do they take into consideration that the sun is either constantly rising or falling in the horizon, so that whatever angle they may adopt is differently circumstanced as regards the sun's rays every day?

As to distance between the rows, when pease are sown in the usual manner—that is, row after row throughout the whole quarter—it may be taken as a general rule that as much space should be allowed between them as the sorts attain in height;—thus, a pea of two feet in height should have two feet from row to row, and so on, up to Knight's tall marrow, which attains a height of from eight to ten feet—which latter should be placed at least ten feet asunder. A much better plan was, we believe, first recommended by the late Mr Cobbett, who is said, by those who seem to know, to have published the best English Grammar of the day; and we can safely say he wrote the best book on cottage gardens which has appeared before or since. His plan with pease was to sow in single rows, twenty, thirty, or fifty feet apart, by which every portion of the crop was fully exposed to the sun and air—the crop hanging, in consequence, profusely from bottom to top. By this means, also, he secured shelter to his other crops, as his pea crop served the purpose of so many temporary screens during the whole summer, at the

very time they were of most importance. There is no loss of ground by this method, for other crops can be planted to within $1\frac{1}{2}$ or 2 feet of the rows—which space is necessary for the purpose of gathering them. Any person of the least observation must have seen that the outside of the first or last row in a continuous piece always produces the earliest, finest, and most abundant crop. There is a great economy of space by sowing pease in the following manner, noticed in the "Gardeners' Magazine," vol. iv., p. 225:—"If only two rows in one place, and two more in another, 15 or 20 feet distant, were sown, there would be four outsides; whereas, if they were all sown together, there would only be two outsides. Two rows in one place occupy 3 feet 6 inches in width, and two rows in another the same, making together 7 feet; but if four rows were sown together, they would take up between 11 and 12 feet of ground. Here there is a saving of nearly one half." Again, let us observe that, without infringing on the rules of rotation, the leguminous plants may nevertheless be grown on the same quarter or division, by sowing the tallest-growing sorts at great distances apart, placing the dwarf-growing ones between, interlining with kidney beans, which attain the height of 18 inches, and with the new dwarf cluster garden-bean of similar height: thus the object of full exposure would be attained, while the rotation would not be interfered with.

Sowing for principal crops should be attended to from the middle of March to the end of July, making a sowing every fortnight or three weeks at latest, where a constant supply is required daily. Some sow one crop just as the last appears above the ground. All this, so far as regards a constant and uninterrupted succession, depends far more upon the sorts sown than on the exact period, because some kinds come to perfection much sooner than others. (*Vide List of sorts, &c.*)

For the latest crops of all, sow on the 1st, 10th, and 15th of August, and 1st of September, choosing dwarf early sorts, for the greater convenience of protecting them, should need be, during November and December, by spreading thin canvass over them on frosty nights.

There are few esculent crops that suffer

so much from the malpractice of too thick sowing as the pea. The autumn-sown crops, of course, require more seed, as the chances they run of being injured by frost or devoured by mice are very great, and therefore that should be taken into account: if they escape these dangers, they can be thinned out, and the thinnings transplanted in spring. We would also remind amateurs, particularly those near towns, that the sparrows will take their tithe of them just as they come above ground, and that provision must be made for this in sowing. Fifty peas to the foot of line in such cases, and of such sorts as Warner's early emperor, Sutton's early champion, Fairbaird's champion of England, and Bishop's new long-podded, will be ample. For very small gardens, Bishop's early dwarf is well adapted, growing only 1 foot in height, and hence requiring no stakes. They should all be sown $3\frac{1}{2}$ inches in depth. The fourth in the above list may be sown at half the above distance, as it sends out lateral branches, and hence requires space for them to spread. Pease are always, in England, sold by the pint or quart, peck, bushel, &c.; in Scotland, often by the pound, when in small quantities. One quart is equal to about 2 lb., and contains of the largest sized peas 1298, and of the smaller 2150. One pint of the small-seeded sorts, as the Frames, Charltons, &c., will sow a row 20 yards in length; and the same quantity of larger-growing sorts will sow a row 33 yards long, on account of their being sown so much thinner. The old practice of treading down the pease, when sown in autumn, should be discontinued, and this the more especially if the ground be wet or the soil strong. The old Scotch practice of sowing in double rows is now seldom seen, at least where anything like good culture is exhibited.

Many cultivators, and ourselves amongst the number, set their pease for general crops singly, as is practised with beans, the larger-growing sorts from 3 to 4 inches apart; and we also, in some cases, plant them in patches of five or six in each, allowing as much space from patch to patch as the pease attain feet in height, each patch assuming, when staked, a pyramidal form: by this means the whole surface is exposed to the sun and air. The

usual allowance for seed is—for the frame section, which includes most of the early sorts, 36 peas per foot of line; marrow-fats, dwarf variety, 24; do. tall, and all of similar habit, 12; blue Prussian, and those of the same size, 18, &c. The depth for main crops should be, for the smaller-sized pease, $2\frac{1}{2}$ inches; for the larger kind, $3\frac{1}{2}$ inches.

To obtain pease early, various methods have been tried: some sow in flat pots or boxes in January, placing them in a cool pit near to the glass, and transplant about the middle of March; others in small 60-sized pots, so as to turn out the balls entire at planting; some follow Bishop's recommendation, and sow on thin narrow strips of turf, burying the turf under them at planting; while many sow in open drain-tiles filled with soil, some on narrow pieces of board, and many nail two boards together in form of a triangular trough about 3 inches deep, fill the same with mould, and sow thereon. At planting, drills are drawn; these troughs are set in them, the sides removed, and the row of pease left undisturbed. The following very excellent mode has been long practised by Mr Drummond, gardener at Blair-Drummond:—About the beginning of February, when he commences forcing peaches, "the border inside the house, on each side of the pathway, is covered to the depth of 3 or 4 inches with cow-dung, gathered from the park; over this is laid 2 inches of decomposed tree-leaves, passed through a very wide sieve, raking level, and beating slightly with the back of a spade: upon this the peas are sprinkled as thick as they will lie together, and covered with sifted leaf-mould 2 inches thick. In the course of three weeks or so the pease are fit for planting out, being from 4 to 6 inches long. A border on the south aspect of a wall is chosen for the first planting, the ground being dunged, and dug deep and fine; furrows are taken out with the spade diagonally across the border; "the pease are then raised from the border of the peach-house with a three-pronged hand-fork," in large pieces, and carried to the prepared drill; "they are then divided by the hand into small patches, drawing each patch longitudinally, then placing it in the cut furrow in the manner of planting box-edgings, let-

ting the roots hang as perpendicular as may be. By this operation very little of the dung and leaf-mould falls from the roots. The earth is then laid over and pressed firmly to the roots, and another furrow made, and drill-planted in the same manner, 9 inches from and parallel to the other, thus forming a double row. A little earth is drawn up about them with the draw-hoe, and they are staked pretty closely, and a few fir-twigs are stuck among the stakes to ward off sharp frosts; these are removed when the weather gets mild. Pease sown on the 1st of February, and transplanted as described above, are fit for gathering about the same time as, or even sooner than, those of the same sort sown on the 11th of November preceding, in the open air, along the bottom of a wall with a south aspect. Pease, by this process, have been gathered on the 26th of May—certainly very early for such a locality; indeed, unusually early for any part of Scotland. Pease are readily transplanted while under 4 inches in height; they may therefore be sown on a warm border, or in a pit or frame covered with glass lights in severe weather, and transplanted in March. This, although not a very general practice, has been in use for above a century. Justice, in his "British Garden Calendar," published in 1759, recommends the practice, and reasons on the advantage of it. Bishop, in his excellent "Casual Botany," suggested sowing them in November on narrow strips of turf, and transplanting them undisturbed at a more advanced period of the season. Pease do not require this trouble; indeed, it is questionable whether the operation of transplanting in the ordinary manner may not be an advantage, as the greater or less degree of injury to the long tap-roots causes them to put out lateral ones, which, taking a more horizontal direction, are nearer the surface, and consequently influenced somewhat by the sun-heat, besides having the effect of causing the plants to send out a greater abundance of roots, and hence enabling them to secure a greater amount of food. The London market-gardeners' practice is good, when they throw up triangular ridges in autumn, and sow a line of pease along the south side, and another along the opposite side, with a view to obtain an early crop

on the south side, should they survive the frosts of winter and spring, on the side next the sun, the crop being accelerated by the radiated heat from the surface: should these fail, those on the northern side seldom do, and give a good crop, though somewhat later. In sowing the general crops during summer, if the ground be very dry, the drills should be well soaked with water previous to setting the pease: this moisture, being covered up, retains the seeds in good condition for a long time, and hastens their germination, which otherwise might as well be in the bag.

Subsequent cultivation.—When the crop has attained the height of about five inches, a little earth should be drawn around the stems, but not so close as to press upon them; it should form a sort of ridge, with a slight channel in the middle. The intention here is not, as in many other cases, to encourage the roots to diverge in a horizontal direction, for they have no disposition to do so; but rather to give a slight support to the plants, until they take hold of the stakes which are to support them. Those crops which are not to be staked require this support the most, and they should have the earth drawn up upon one side only, that the haulm may be thrown to one side, which will both facilitate the operation of gathering, and will keep the ground clean between them at the same time, while it supports the neck of the plants better than if the earth were drawn up on both sides.

The advantage of stopping pease is much greater than is generally admitted, as is also that of thin-planting the seed. If the seed of most kinds be planted 6 inches apart, instead of being sown, as they generally are, a saving of seed to the extent of five-sixths will be the consequence; and if the plants, even of the tall-growing kinds, are stopped when they have attained the height of 2 feet, and when they have made three joints after this stopping—if stopped again and again, after every three joints are formed, until the period when they are wished to produce their pods, an increase of crop, at least fourfold, will repay the trouble; and if several kinds were sown on the same day, this stopping will bring them into bearing in succession, and just at the periods when the crop is desired. Whenever stopping ceases, the pease will flower and set their pods. It

will, however, be necessary to look over the crop occasionally, and remove any stray blossoms that may appear; for none should be allowed to set until the general crop is wished for. From this a good practical lesson may be learned: the stopping gives strength to the plants and encouragement to the roots, so that, when the crop is really wanted, both are in a much better condition to throw strength into the crop than if they were allowed to rush up into blossom at once. In the event, also, of a wish to retard the ripening of a crop to any particular period, timeous stopping will effect this with greater certainty than repeated sowings made in the usual way.

Staking is the next operation in culture, and it is of great importance it should be done early, before the stems fall over. Such an untoward circumstance often ruins an otherwise good crop. Newly transplanted pease, brought forward in a slight heat, require this attention at the time they are planted, on account of the shelter afforded them; and pease sown in autumn, as soon as they begin to break through the surface, or even before, demand the same attention. It is of consequence that the supports, whatever they may be, be equal in height to the height the variety attains. Many contrivances have been thought of for supporting this crop, with a view to do away with the not very elegant appearance of the stakes. Posts driven in the lines, having wide-meshed netting suspended from them, and hanging down both sides of the line, is one of the most feasible plans. Hexagon wire-netting, attached to iron props, has been suggested, and no doubt would do well were expense no consideration. Lines of cord stretched along the rows, and fixed to upright rods, are sometimes used; but by far the most general is branches of hazel, beech, or other deciduous trees. These, however, are very perishable. Branches of yew, lilac, or privet are the most durable, always excepting the larch, which makes the best of all. Whenever, therefore, the prevailing disease attacks young larches, of from 6 to 10 feet in height, to the extent of rendering their cutting down expedient, lose not the chance of securing them. They require little preparation farther than pointing the root end, topping them all to the required heights, and

switching the side branches off on both sides, as if switching a hedge. We have had such in use for six years.

Whichever of these be employed, they should be stuck firmly in along both sides of the crop; and if placed in a slanting direction, so much the better for the tendrilled branches attaching themselves to them. They should be of equal height, and all straggling side twigs should be cut off for appearance sake.

Considerable advantage arises from topping the plants when they have shown a sufficient number of blossoms. This stops the growth of the haulm, and diverts the whole energy of the plants to the formation and development of the pods. In dry weather, pease often require water; indeed, a good soaking to all crops in warm dry weather, whether they appear to require it or not, will be found of great advantage in preventing mildew and swelling out the crop. A humid climate suits the pea, and hence the longer continuance of our crops in Scotland than in the southern parts of England.

Soil and manure.—The pea comes earliest to maturity in light rich soils abounding in humus; hence the practice of adding decomposed leaves or vegetable mould to the roots at transplanting has the beneficial effects stated above. For general crops, a rich hazel loam, or deep rich alluvial soil, is next best; but for the most abundant of all, a strong loam, inclining to clay. For early crops, mild manure, such as leaf-mould, should be used, unless the soil is not exceedingly poor. If the soil is very poor, stronger manure should be employed. For general crops a good dressing may be given; and for the dwarf kinds, such as Hair's mammoth, Bishop's new long pod, the soil can hardly be too rich. If poor, they do little good, particularly if, in addition to this, they be thickly planted.

The crop should be gathered as it becomes fit for use, for if even a few of them begin to ripen, young pods will not only cease to form, but those partly advanced will cease to enlarge.

Gypsum has been applied to pease as an auxiliary to farmyard manure, and the advantage is marked; and we have no doubt that, if it were applied as a top-dressing to the rows, at the rate of one cwt., and at a cost of about 3s., to a quarter of an acre, during the early stages of their

growth, much benefit would result from its application in that way and at that period. It has much improved crops suffering from mildew, and those which have come up ill, or which have been injured by late spring frosts. It is more immediate in its effects when applied either before or during rain. Top-dressing with nitrate of soda has also been found of advantage under similar circumstances. The best manure, however, to be applied to pease, provided the ground stands in need of enrichment, is guano; and we may once for all remark here, that, of all special manures, it is the *best* for almost all garden crops. It contains the ingredients required by most plants, and just in the proper state. We have used it with great advantage by following the practice of the Peruvians, who apply it to crops at three different times—viz., at the time of sowing, again when the plant is nearly half-grown, and a third time just previous to the ripening of the seed. With pease we have strewn a small quantity along the bottoms of the drills, which were drawn about 2 inches deeper than usual. This was mixed with soil, and about 2 inches of the common soil placed over it, upon which the pease were sown, and covered up in the usual manner. The quantity used was three pints of guano to a row 50 feet in length. The soil was dry at the time of sowing, and for a week afterwards, when genial showers fell, which we calculated would begin to render the guano soluble about the time the young rootlets had penetrated to its *whereabouts*. The plants grew stronger than those in the adjoining rows, which were not thus treated, and continued to keep the lead of them. When about a foot in height (the sort was Bishop's new long pod), $1\frac{1}{2}$ pints of guano were dissolved in a tub of water containing 100 quarts: the row was watered with it. Just as we had gathered the first dish of pease, a similar quantity was applied. The pease continued to produce pods three weeks longer than the neighbouring rows, and the pods were much better filled and the pease larger, the joints of the straw much closer together, and the stems of the straw itself nearly half as thick again as under ordinary circumstances. Applying the guano dry under ground prevents the escape of

its ammonia: the moisture in the soil renders it soluble; but in dry weather water should be applied to effect this the more speedily. The other rows had the same quantity of pure rain-water applied to them, and the soil was the same. A similar result followed the same experiment on beans, and on various other culinary crops. Our opinion is, that with guano, if the soil be in a proper state, and in the absence of stable manure, we are quite independent of all other so-called manures whatever; for although, for some purposes, they do some good, yet they can never be, like guano, of universal application.

Forcing.—Even in our present state of horticultural advancement, the pea is not very generally forced: it is, however, in some large establishments, grown in pots, boxes, and heated pits. Being a native of the more temperate regions, it does not prosper in much heat; that of a glass-case or late peach-house seems a proper medium. No doubt, ere long, pits will be constructed for the express purpose; and such structures as Mr Rivers' orchard-houses would be almost all that would be required. The very earliest and most dwarf varieties (vide *Lists of approved sorts*, &c.) should be chosen. A rich vegetable soil should be employed. Pots with three or four seeds in each is the most probable means of attaining a crop. A temperature commencing at 40° and 50° during the day will be sufficient until the pods are beginning to form, rising gradually afterwards from 55° at night to 70° during sunshine. Forced pease should be invariably transplanted, to check luxuriance. If sown towards the end of October, with good management and in abundance of light, gathering may be expected by the 1st of March. After the pods are set, a little stimulant should be applied in the shape of liquid manure.

Approved sorts, and their qualities.—It is difficult, in attempting to do anything like justice to a subject so involved in confusion as the pea tribe has long been, and still is, to know whether it would be best to give a list of those names which have been sufficiently proved to be mere synonyms of one another, and of those kinds which are now quite unworthy of longer cultivation, or to confine ourselves to a notice of those which are really distinct, so far as their period of ripening, height, colour, and size can be considered as distinctive marks, and which are, on account of one or more of these characteristics, most deserving of cultivation. We

think the latter mode will be the most generally useful.

As an instance of the deceptions carried on in the pea-trade, we may notice that of the Egyptian or mummy pea, said to have been raised from seeds taken out of a vase hermetically sealed, found in a mummy-pit in Egypt, computed to have been kept in that state about three thousand years, which has been found no other than the well-known branching marrow of our own gardens.

From the experiments made about two years ago in the gardens of the London Horticultural Society, under the direction of Mr Thomson, who sowed no less than 235 reputed sorts, all of which were at that time enumerated in seed-lists, only twenty-seven of that number were selected as being really useful. This selection the editor of "The Gardeners' Chronicle" at that time thought might safely be reduced to half-a-dozen. During the years 1850-51, we sowed upwards of one hundred reputed sorts in the gardens at Dalkeith—fifty sorts in each of these years. They were in each case sown on the same day (25th March), in the same soil, and under the same circumstances. Out of that number we selected twelve as being truly distinct and useful; yet one half of these would be quite sufficient for even our use, who require them during the longest possible period. New sorts are yearly springing up, and therefore it would be injudicious not to give them a fair trial; for as we progress in pea-culture, as in everything else, we may naturally expect that improved sorts will arise and take the place of others that may be inferior. We have elsewhere stated that the height to which they grow regulates pretty nearly the distance at which they should be set apart, either between the rows, or individually in the line.

The following are the names of Mr Thompson's select list of eleven out of the above twenty-seven as determined at the above date; the heights and properties, &c. we have added:—

1. *Prince Albert.*—From 2½ to 3 feet, according to soil; a white-seeded pea, forming with Kent's early, early here, early Warwick, early May, and a lot of others, a section of which the true early frame is the type, and comprising our earliest sorts; moderate croppers; pods contain from eight to ten peas each.

2. *D'Avvergne.*—4 feet; seeds white; remarkable for its long crooked pods, and the great number of moderate-sized peas each pod contains; one of our best for second or general crops. This is identical with Richardson's eclipse and Torwoodlea, two Scotch synonyms.

3. *Dancer's monastery.*—4½ feet; seeds white; a good profitable sort for a second or general crop; peas of moderate size, rather above medium.

4. *Bishop's new long pod.*—2 feet; seeds white. A most abundant bearer, producing a succession of pods during most of the pea season. Like all dwarf peas of its class, it requires a rich soil, and from 4 to 6 inches between the seed in the line. We have had this pea producing a good supply for three months in succession. It is one of the most valuable sorts for small gardens, and for domestic use: its only

fault in large establishments is the large size of the peas, but, although disliked by cooks on that account, it is much prized by them for many purposes. It originated with the late Mr David Bishop, author of "Casual Botany," and is a hybrid between Bishop's early dwarf, a pea of only 1 foot in height, and one of the marrow-fats, carrying in itself the characters of both its parents.

5. *Fairbeard's surprise*.— $5\frac{1}{2}$ feet; seed bluish; a profitable sort for a second or general crop. Pods thick, roundish, containing from seven to nine peas of excellent quality; the same as Fairbeard's early surprise.

6. *Victoria marrow*.— $5\frac{1}{2}$ to 6 feet; seed bluish; an excellent sort for a general crop. Pods nearly 4 inches long, generally in pairs, containing from seven to eight large peas each; one of our very best peas.

7. *Bedman's imperial*.—3 feet; seed large; bluish green; called also Bedman's dwarf imperial; very similar to Flack's dwarf victory; perhaps scarcely worth growing as distinct sorts. Very prolific; peas large; excellent for green-pea soup.

8. *Flack's new large victory*.—Seed large; bluish green; 3 feet. Mr Thompson makes this distinct from the last. It seems to us to be a distinction without a difference. There would be, however, no loss in growing both these excellent peas under different names—much less, at least, than scores of others. Pease generally six in a pod, and of excellent quality.

9. *Knight's tall marrow*.—6 to 7 feet; seed large; wrinkled or indented when dry; white. Often called Knight's tall white marrow, to distinguish it from Knight's tall green marrow. Originated with the late Mr T. A. Knight (*vide* sect. PROPAGATION BY SEED). Very much esteemed for its productiveness and fine flavour. Like all the tall marrows, only fit for a large garden, and then to be grown in single rows, at a great distance apart. Adapted for general crops. Pods large—from seven to nine peas in each; known also as Knight's late, Knight's tall green marrow, Knight's tall blue marrow.

10. *Fairbeard's champion of England*.—5 to 6 feet; seed large; wrinkled when dry; bluish green. One of the best of the wrinkled marrows, and well adapted for general crops, as well as early ones, being about as early as the Charlton. From seven to eight large peas in a pod.

11. *Knight's dwarf marrow*.—3 to 4 feet. There are two varieties of Knight's dwarf marrow, differing, we think, only in the colour of the dried seed, the one being white, the other greenish. However, either is valuable for a general crop. The bluish green variety appears to be preferred by Mr Thompson. Like all the marrows, the seeds are large. Pods large, containing six peas in each, and of excellent flavour; quite sugary.

To these we shall add from our own memorandum, resulting from our trial above referred to—

1. *Hair's dwarf mammoth*.—2 feet; seed large; wrinkly; bluish green when ripe. Equal in flavour to any of Knight's marrows, hitherto considered the best in this respect. A most

productive pea, continuing, like Bishop's new long pod, in bearing for a long time, but somewhat later. Indeed, it is a truly second or general crop variety. It is larger in pod than Knight's dwarf marrow, and about seven days earlier. It requires highly enriched soil, and the peas to be planted from 4 to 6 inches apart in the line, as they branch out in the manner of Bishop's. One of the most valuable for small gardens and private families, and, like the latter, although large when sent to the table, if not too old, eats deliciously, having a great deal of the marrow property about it.

2. *Lynn's prolific*.—4 feet; seeds under medium size; wrinkled, and having a dark eye when ripe; seemingly a distinct variety of marrow; very productive, and stands drought well. Suited for a general crop.

3. *Sutton's early Goliath*.—4 feet; seed and pod large; in flavour resembling Knight's marrow-fats. Suited for a general crop, as it is an abundant bearer.

4. *Early Charlton*.—Too well known to require description, having been in cultivation for upwards of a century. We notice it here on account of its great hardiness and fitness for autumn sowing, to stand over the winter. How will those opposed to the doctrine of acclimation account for this? Originally it must have been as tender as the early frame, its constant attendant, which, like it, is also hardy; and both, with the exception of Hamilton's November prolific (which is no other than seed selected from the Charlton), stand the winter better than those of more recent origin.

5. *The true early frame*.—The type of the early Kent, of all the really early sorts, and probably of the next two.

6. *Beck's morning star*.—3 feet; seeds small; podding early and largely; pease a proper size for a first-rate table.

7. *Sutton's early champion*.—3 feet; resembling the last, only somewhat earlier.

8. *Burbage's eclipse*.—From 18 inches to 2 feet; seed large—from five to six in a pod; blue when ripe. An excellent bearer, having the young pease of a very proper size. Known also as Stubb's dwarf. Not so early as Bishop's new long pod; it is, however, a good dwarf pea for summer crops.

9. *Groom's superb dwarf blue*.—Under 2 feet; the most productive of its height; well adapted for small gardens, as a second cropper.

10. *Woodford's dwarf*.— $2\frac{1}{2}$ feet; seed medium size; very dark green when ripe; a most abundant bearer, and well suited for small gardens as a principal crop.

The dwarfest of all peas are, the Spanish dwarf, Bishop's early dwarf, Thompson's early dwarf. These seldom exceed 1 foot in height, and in rich ground give fair returns.

11. *Bellamy's early green marrow*.—4 to 5 feet high; pods cylindrical, straight, containing generally six to seven peas; a good bearer and excellent pea.

12. *Adamson's matchless marrow*.—About 5 feet in height; pods curved, flattish, containing from six to seven peas. As early as the Charlton, and an excellent bearer. The following are

so nearly related to it that it would be useless to grow them in the same garden—viz., tall Prussian, blue union, green nonpareil, tall imperial, tall blue imperial, tall green imperial, new tall imperial, Spanish patriot.

13. *Blue Prussian*.—A well-known excellent pea. We notice it here merely to give the synonyms—early Dutch green, fine long-podded dwarf, dwarf blue Prussian, royal Prussian blue, Prussian prolific, and green Prussian.

14. *Woodford's green marrow*.—3 feet in height; pods large, flat, containing six large well-flavoured peas, and an excellent bearer.

15. *Dwarf imperial*.—4 feet in height; pods large, containing from eight to ten peas; a good bearer, and excellent for a late crop. Like all good sorts, has a host of names; viz., sabre, blue sabre, new sabre, dwarf sabre, imperial, blue imperial, dwarf green imperial, new improved imperial, new improved dwarf imperial, new dwarf imperial, new long-podded imperial, dwarf blue prolific, green nonpareil, blue scimitar, Sumatra.

16. *Dwarf green marrow*.—A good pea, but rather inferior to Knight's dwarf marrow. It is to be found in the seed-shops under the following names—New green nonpareil, Prince's superfine summer, Wellington, extra green marrow, new green, early dwarf green, early green, new early green, royal dwarf marrow, Holloway marrow-fat, green rouncival.

17. *British queen*.—Height from 4 to 5 feet; pods large, containing seven very large peas in each; sometimes a single pea measuring $1\frac{1}{2}$ inches in circumference. Hence too large for a first-rate table, but excellent for private family use.

18. *Hair's defiance Knight's marrow*.—4 feet high, remarkable for its strong habit, should be planted from 4 to 6 inches apart in the rows, and each row 4 feet distant. A remarkably profitable pea, of large size, and continuing long in a bearing state.

19. *Tall crooked sugar*.—Pois sans parchemin à grandes cosses—grosse schottige zuckererbse; a late rambling sort.

20. *Dwarf crooked sugar*.—Pois sans parchemin ou mange tout—zweg zuckerschotte.

To those who intend growing this section of pease, we would specially recommend—

21. *Dwarf sugar, or Ledman's dwarf*.—Growing about 3 feet high; pods long, cylindrical, and slightly curved; rather late, but a good bearer.

22. *En eventail*.—About 1 foot in height; assuming the habit of Bishop's long pod, and, like it, branching close to the ground; a moderate bearer.

23. *Tamarind or late sugar-pea*.—The best bearer, although the latest, in the section; nearly 4 feet high; pods from 4 to 6 inches long, proportionably broad, and slightly curved.

The French grow many varieties of edible podded peas; and although suitable to their taste and climate, they are not so with us. The Dutch grow two sorts, and even these, for the most part, are found so tender, even in Holland, that they are generally produced under glass.

Should, however, Messrs Weekes & Co.'s new pea, recently brought into notice, turn out as

represented, it will, as an edible podded sort, supersede these and all others of a like property, in bulk of produce at least, and may be found far more economical to cultivate, as an article of food, particularly for cottages, than any at present known. It is described as a new hybrid (the parents, however, are not stated), attaining the height of 4 feet; stem slender; great bearer, and exceedingly ornamental for its flowers and singular pods, which measure $5\frac{1}{2}$ inches in length, and $1\frac{1}{4}$ inches in breadth; of a glaucous green colour, each containing seven seeds. It can either be cooked in the ordinary way (boiled, when young, whole, pod and all), or left to attain a more advanced growth, and then cut up and eaten like a French or kidney bean. Being so much harder than either the kidney bean or scarlet runner, and yielding a produce even exceeding the latter (which at present is, we think, were it not for the short period of its existence, the most profitable vegetable that the cottager or small gardener can grow), this would even excel it for such a purpose. Should this new pea, upon further trial, equal the specimens grown last year, it will no doubt be considered the greatest novelty of the pea tribe that has yet appeared.

The following sorts stand in good estimation amongst growers:—

Early Warwick, $3\frac{1}{2}$ feet—a sub-variety of early frame; Thurstone's reliance, 6 feet—one of the largest peas in cultivation; scimitar, 3 feet—an old variety, long podded, and fills well; ne plus ultra, 6 feet—a green wrinkled marrow; old dwarf marrow, $3\frac{1}{2}$ feet; tall green mammoth, 6 feet—similar to Hair's dwarf mammoth in pod; matchless marrow, 5 feet; Melford marrow, $4\frac{1}{2}$ feet.

"Warner's early emperor, Warner's early conqueror, early Bedalean, Essex champion, early railway (or Stevenson's railway), and early wonder, have been proved in the gardens of the London Horticultural Society to be all varieties of the old early frame, and possessing no one merit over the original. Danecroft rival, Danecroft early green, Farnes' conservative, green marrow, and the transparent pea, are by Mr Thompson considered to be all one variety. Clark's Lincoln green podded new early marrow—no marrow at all, but one in the way of the early frame. American dwarf, a good bearer, ripening about a week or ten days later than Bishop's new long pod—a very good dwarf variety. Early surprise, from a foot and a half to 2 feet in height; pods large, thick, containing generally six large blue peas, the plants having the strong stems and vigorous habits of the marrows. Early blue surprise identical with Fairbeard's early surprise. Queen of England, a sort of white marrow, inferior to the British queen. Waite's king of the marrows resembles the ne plus ultra. Great Britain similar in every respect to Knight's tall white marrow. Hunter's new marrow, about the same height as Knight's dwarf marrow; pods roundish or a little flattened, containing about six large peas; larger than Knight's; of very sugary quality; when dry, indented; yellowish white; a good bearer."—*Ex Jour. Hort. Soc.*, vol. v. p. 283.

From experiments made in the London Horticultural Society's garden on the following

peas, their period of coming to perfection was ascertained as follows :—

Cornick's Prince Albert, Warwick,	Sown January 4,	Came into flower April 1.	Pods gathered from May 14.
	~~~~~ January 4, . . . . .	~~~~~ April 13. . . . .	~~~~~ May 28. . . . .

—These are sub-varieties of the early frame, differing only in time of coming to bear.

Prince Albert, . . . . .	Sown March 28, . . . . .	3 feet in height, . . . . .	Fit for use June 19. . . . .	One of the earliest of peas. . . . .
Bishop's early dwarf, . . . . .	~~~~~ . . . . .	9 inches . . . . .	~~~~~ June 26. . . . .	Very inferior sort. . . . .
Early race-horse, . . . . .	~~~~~ . . . . .	3 feet . . . . .	~~~~~ June 29. . . . .	An inferior var. of early frame, . . . . .
Shilling's grotto, . . . . .	~~~~~ . . . . .	3 feet . . . . .	~~~~~ June 29. . . . .	An excellent pea. . . . .
Dwarf green marrow, . . . . .	~~~~~ . . . . .	3 feet . . . . .	~~~~~ July 10. . . . .	A good cropper. . . . .
Blue Prussian, . . . . .	~~~~~ . . . . .	2 feet . . . . .	~~~~~ July 10. . . . .	A good bearer. . . . .
Matchless marrow, . . . . .	~~~~~ . . . . .	3½ feet . . . . .	~~~~~ July 17. . . . .	An excellent large pea, and productive. . . . .

—The heights given above are those to which they attained in the Society's garden.

The following experiment regarding the precocity of the following peas was made in the garden of the Horticultural Society by Mr Thompson. Three varieties of early frame, amongst which was the true early frame from Paris, were sown in continuous rows on March 13. They proved to be the same, and were fit to gather June 9. Early Kent, fit June 2. Warner's early emperor, fit June 4. The two last are varieties allied to the early frame, the early Kent differing from it in being a week earlier, and not so strong-growing. "Warner's early emperor is not quite so early as the early Kent, and its growth is intermediate between the early Kent and the early frame. Fairbeard's early surprise was sown April 23, and was fit to gather June 27; but the early frame, sown at the same time, was fit June 19. Fairbeard's is therefore eight days later than the early frame, and consequently, according to the foregoing statement, it would be a fortnight later than the early Kent." This pea, therefore, cannot rank amongst the earliest, but will hold a good place in the second early section along with the old Charlton, to which it seems related.

The following six varieties of dwarf pease will form a good succession, and will be found suitable for a small garden, or where ground is scarce:—The true early frame, Fairbeard's early surprise, Groom's superb dwarf blue, blue Prussian, Milford marrow, and Knight's dwarf marrow—sown in the order in which they stand.

*Insects and diseases.*—The greatest enemy to the pea tribe is the pea weevil. This destructive family of insects, the weevils, are enough of themselves to eat up the whole vegetation of the globe. M. Schonherr, a celebrated Swedish entomologist, spent thirty years in investigating their economy; the results of his investigations have been published, and occupy no less than 7000 pages, octavo, in print. Of this formidable host we have between four and five hundred species existing in Britain. Two of these, *Sitona lineata*, the striped pea weevil, fig. 7; and *Sitona crinita*, the spotted pea weevil, may often be detected eating the young leaves and stems as

soon as they appear above the ground, particularly in dry hot weather. These pests will, in general, be found in full operation in June. The remedies suggested by the writer of a series of articles on entomology in "The Gardener's Chronicle" are worthy of notice. "Any remedies, therefore," he says, "which we can suggest, must have for their object either the destruction of the perfect beetle, or the protection of the plants—neither of which is easy.

Fig. 7.

STRIPED PEA WEEVIL.

As to the former, we scarcely think that any trap could be employed into which the insects would creep at night (like damp grass, into which the wire-worm creeps; or bits of potatoes put into the ground, to which, as food, the same insect is enticed); possibly, however, dry hay laid along the rows might entice them into it as a retreat. Another means of destruction suggests itself, in connection with the habit of the insect of falling to the ground on being surprised. A bag-net about 2 feet long, and with one side flat, so as to allow of its being placed on the ground close to the sides of the rows of the pease, would, we think, be serviceable. This might be run along the rows, the plants being slightly swept over by a switch held in the right hand, the handles of the bag-net being held in the left hand; or, perhaps, by merely running the net along or across the rows, they might be jerked into it. As to the protection of the plants, soot and pounded lime have been suggested to be sprinkled over them, previously wetting them by a watering machine. In this respect the same kind of remedies must be used as have been proposed against the turnip flea-beetle, having for their object the rendering of the plant disagreeable to the insect by a coating of matter offensive to its taste; or by forcing forward the growth of the plant as quickly as possible. We may also suggest the possibility of advantage resulting from drawing a cloth covered with pitch or tar

over the rows of the pease: the insects might become fixed to the cloth, and might be easily destroyed."

Besides these there is a small beetle, *Bruchus pisi*, L., fig. 8, which deposits its egg within the pea, which serves the grub for food, and is thus destroyed. It abounds most in dry seasons, and for it there seems no great chance of a remedy. It is, however, not very injurious to us in its attacks.

The description given by Mr Curtis, in the "Journal of the English Agricultural Society," vol. vii. p. 408, of this insect is good:—"They pair in summer, whilst

the pease are in flower, and producing pods; the females then deposit an egg in almost every pea that has almost just formed. From the outside of these peas, when arrived at maturity, they do not appear damaged; but, on opening them, one generally finds a very small larva, which, if left to repose, remains there all the winter and part of the following summer, consuming by degrees all the internal substance of the pea, so that in the spring the skin only remains; after which it is transformed into an insect, with scaly wing-cases, which pierces a hole in the skin of the pea, from whence it comes forth and resorts to the fields sowed with that pulse, in order to deposit its eggs in the new pods."

The American mode of destroying the pea bug, *Bruchus pisi*, is thus stated in "Hovey's Magazine of Horticulture":—"Immediately after gathering the seed, it is subjected to the action

of boiling water for one minute; by this means the grubs, or larvæ, which at this time are just below the integuments of the pea, are destroyed without injury to the vitality of the seed."

Another species, *Bruchus granarius*, fig. 9, is often found in seed-rooms, in

seed-peas; and the holes in the pea and bean from which it issues after its transformation, are frequently occupied by the caterpillar of the white-shouldered wool-moth, *Tinea sarcitella*, fig. 10, the well-

known domestic pest, which lays its eggs on all manner of woollen stuffs, to the great annoyance of every thrifty housewife. They are often found in the seeds of pease and beans, and, in company with the *Bruchus granarius*, and the larvæ of a species of saw-fly, work sad destruction in the stock.

The *Bruchus granarius* is thus described in the "Cottage Gardener," vol. iii. p. 13:—"These holes in the peas and beans are made by this beetle, which is produced from a grub or caterpillar, which has eaten away the vital parts of the seed; and when it has passed through the chrysalis state, and given birth to this beetle, the latter makes the hole in order to escape into the open air, there to perpetrate more mischief upon the growing crops. The body of the beetle is a dull brown, but the elytra, or wing-covers, are black, dotted with white, but scarcely perceptibly so, unless magnified, as in our drawing. Naturally it is the size of the smaller figure, and is scarcely two lines long. The antennæ are eleven-jointed, black, and thinnest near the head, where they are also tinged with red. The head droops, the eyes are prominent, the fore-legs are rusty coloured. The female pierces through the pod of the pea or bean whilst very young, and often deposits an egg in each seed." This insect may be destroyed by the American mode of dipping the seed in boiling water, as noticed above.

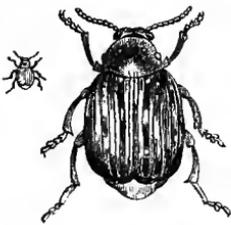

The pupæ of the fly *Phytophiza nigricornis*, the black-horned leaf-miner, fig. 11, feed on the

BLACK-HORNED LEAF-MINER.

parenchyma of the leaf, causing minute brown spots in it. The only mode of riddance appears to us to be picking off the infected leaves and burning them, to prevent the further breeding of the insect. The cross lines show the natural size of the insect.

The next serious enemies to the pea are mice and rats. As preventives, rubbing the pease with powdered resin, placing over them in the drills chopped furze, dusting them with lime, sowing charcoal dust along with them, have all been tried with more or less benefit. No plan is, however, so effective as catching the vermin in traps. Poison is dangerous, and seldom so carefully concealed but that some poor bird or other falls a victim to it. The best traps are the cage trap, baited with toasted cheese or broiled bacon; the next best, the old figure four trap, which has been used for this purpose above two centuries; or the suspension trap, the most simple of any. It is constructed by soaking a few peas in warm water, and when they have

begun to grow, a pretty strong thread is passed by a needle through the peas, leaving two of them on every 9 inches of thread, at which lengths the thread is cut off. Tie a knot at the end of each length; take two pieces of straight wood, cut them into 1-foot lengths, make a slit about an inch deep in the top end of each, and stick them in the ground near the line of pease. The thread is then drawn through the slit ends of the sticks, and a brick is placed with one end resting on the ground, and the other resting on the thread about 3 inches from its end, the two peas on the thread being near the middle of the brick, and 2 inches apart. The mouse, in attempting to eat or take away the peas, cuts the thread, and lets the brick down upon itself. It has been stated that mice will not take peas until they have begun to vegetate, and this is given as a reason for sprouting the bait: we do not think them so very fastidious; but if it is really so, they may be set the one way as well as the other. If people would only persevere with any of these traps, they would soon rid their garden of such pests, without the dangerous expedient of using poison. Phosphorus paste may be safely used in gardens for the destruction of both rats and mice. It is thus prepared: To 8 parts of phosphorus, liquified in 180 parts of lukewarm water, placed in a mortar, add immediately 180 parts of rye-meal (any other meal will do as well); when cold, mix them up with 180 parts of butter and 125 parts of sugar. These animals will greedily devour this mixture, after which they will swell out and die. It may be kept for many years without losing its efficacy, and can never injure human beings on account of the smell. This receipt was published some years ago by order of the Prussian government. Meal, butter, and sugar, mixed dry with plaster of Paris, and laid down where damp cannot affect it, will have a similar effect. The animals eat it readily. It soon afterwards causes in them a great thirst; as soon as they take water, the plaster of Paris powder swells out and bursts them. Pease, beans, or any other grain, steeped for several hours in water in which nux vomica has been boiled, and placed in the way of mice, destroys them without even endangering the life of the cat that may afterwards eat them.

Amongst the feathered tribe, the sparrow, tomtit, chaffinch, and jackdaw are very destructive to pease at most seasons, but particularly so in spring, when their other kinds of food are less plentiful. The three first of these we can ill dispense with, because of the valuable services they render us in the destruction of myriads of even more formidable enemies during summer; as for the latter, we can hardly say a word in his favour, further than that we know God made nothing in vain; and even this "gentleman in black" may be of far greater service to us, in some less direct way, than we may be aware of at present. We never destroy birds, believing them far more useful than hurtful, which we hope to show more clearly when we come to speak of fruit and fruit-trees buds. To protect young pease in spring, we dust the rows over every morning, or every second one at furthest,

with a little hot lime in powder, so as to render them quite white. Our mode of application is to have a stock of lime in a dry place, and to send a boy with a thin canvass bag in each hand, containing the lime in powder, and as he passes along between the rows, he shakes the bags over the pease, when the finer particles, passing through the canvass, powder the pease quite white, in which state these creatures will seldom touch them. This process answers another end—it greatly saves the crop from the pea weevil. The operation is best performed when the plants are dry, else the caustic property is soon destroyed. As the attacks of birds take place generally soon after daybreak, the dusting is in general done in the evening previous; but, no doubt, it would be more effectual if done soon after daylight in the morning. The jackdaw not only crops off the tops of the young plants, but, preferring the seed, it with great sagacity often begins at the end of a row, and abstracts every pea in the line. Liming the surface pretty thickly tends to keep them away, but no means are so thoroughly effectual as having wire cages, of a semicircular shape, and in lengths of from 6 to 8 feet, or more, to place over the drills, and these can most readily be thus constructed: Take a web of octagon wire-netting, 18 inches in breadth, cut it into convenient lengths, lay them flat over the garden roller or any other cylindrical body, bend them down at the edges, and by this mode a dozen of cages may be made in half an hour. Such cages are of vast importance in a garden: they not only protect pease from the attacks of birds, but they protect all other crops in like manner, and are valuable for laying over parsley, endive, young cauliflower plants, lettuce, &c., during winter, when a little litter is laid over them, and frost thus repelled. The litter can be removed on fine days, and put on again when required, without injury to the crop. Such netting, 18 inches wide, costs 9d. per lineal yard; and cages so formed will last for years, if not wantonly injured when out of use.

In forming these cages, it will be of advantage, for giving them greater strength for moving about, as well as for keeping them in proper shape, if a bar of round  $\frac{1}{2}$ -inch iron be secured along their bottom sides—which can readily be done by a handy labourer, by splicing the edges of the netting to the bars along their whole length, and welding on a cross-bar at each end of the same sized bar, and one or two, according to the length of the cage, across from side to side. Such cages are next to invaluable, as means of protecting from cold and cutting winds all newly-planted crops in lines, as a few evergreen branches may be tied tightly to them, so as to prevent their being blown away; or waterproof canvass, or asphalt felt, may be employed when keeping the crop dry is an object. Two laths of wood may be used instead of the rods of iron; but they, of course, would be less durable.

We were driven to this expedient some years ago, when grievously persecuted by pheasants, and where to have killed one would have been accounted little less than a high misdemeanour.

The jay is a sad plunderer of early pease, and where they abound, will have the first fruits of the crop in spite of fate. They are, however, becoming scarce in the country, and in some localities are rarely seen. The same may be said of the wood-pigeon, the most voracious of all birds. We hesitate not to shoot *them*. They were designed for food, and in no way are they better prepared than stewed with green pease.

Another enemy of the pea is  
The mildew *Erysiphe communis* var. *Leguminosarum*, a parasitic fungus. The cause of its appearance was correctly enough determined by T. A. Knight forty years ago. He says—“The secondary and immediate cause of this disease has long appeared to me to be the want of a sufficient supply of moisture from the soil, with excess of humidity in the air, particularly if plants be exposed to a temperature below that to which they have been accustomed. If damp and cloudy weather, in July, succeed that which has been warm and bright, without the intervention of sufficient rain to moisten the ground to some depth, the crop is generally much injured by mildew.”—KNIGHT'S *Horticultural Papers*, p. 206. While engaged in the production of those excellent peas which bear his name, he proved this theory by warding off mildew by copious waterings of the roots. The fashionable remedy at present is the use of one of the rival sulphurators. This no doubt subdues the disease, but it does not remove the cause.

*General remarks.*—Early crops of peas derive great benefit from reflected heat when planted at the bottom of a south wall. It is necessary, however, when warm sunshine follows cold frosty nights, to shade the pease from its influence an hour or two in the morning, or to sprinkle them with cold water if they have become at all frozen. Such precautions are also necessary when they are sown on ridges or sloping banks facing the south, which is often done, and with evident benefit in forwarding the crop. Now that glass is so cheap, we see little reason for those matter-of-chance practices, when a better end would be attained by covering the rows of pease with a narrow glass frame, made of a triangular form, and glazed on both sides, or on one only, according as they may be used, on rows running from north to south, or from east to west: in the latter case, such frames may have glass in the south side only.

The saving of seed is an important matter, and is confided to a class of cultivators known as seed-growers, many of whom will have from 10 to 40 or 50 acres under this crop. Some of the London trade have ground of their own, others rent ground; but by far the greater number contract with seed-growers, supplying them with the genuine varieties, visiting the crop from time to time, sending proper persons to *rogue* or pull up all spurious plants, and generally to report progress. The expense incurred for labour and rent, taxes, &c., is great; so much so, indeed, that one wonders how a pint of pease could be purchased for such a trifle. Private growers do not economise by saving their own pease for seed, unless they have, by

keen observation, detected one or more plants possessing more than ordinary merits; then they are right in carefully saving those, for in this way, for the most part, have all our finest peas been produced. Their being ripe will be readily discovered by the straw beginning to dry up, and the pods and peas showing evident symptoms that they are ready for housing. If the quantity be small, put the pods, with the peas in them, into canvass or paper bags, and suspend them to the roof of a dry and airy seed-room. If, however, the quantity be large, leave the pods attached to the haulm, and stack them by till the time of sowing or selling, when they may be thrashed out like other grain. Peas kept in the pod will retain their vegetative action for two or three years, and hence those sent to the colonies should be retained in the pods for greater preservation. When taken out of the pod, even when perfectly ripened, they rarely vegetate after eighteen months, and many not at the expiry of one year.

Pease in a green state are with difficulty sent to a distance, as, when packed closely together, fermentation speedily takes place. This is one of the causes why imported pease, and many of those brought from a distance to our markets, are discoloured, devoid of flavour, and, worst of all, very unwholesome to eat. Pease sent to a distance should be packed in open baskets, not in boxes, and laid in layers not more than 2 inches thick each, and, between such layers, a thin stratum of dry fern or straw should be placed.

The European names are, Pois, in French; Piselli, in Italian; Ervilhas, Portuguese; Erbse, German; Pesoles, Spanish; and Erwt, Dutch.

The quality of the garden-pea as a nourishing article of human food, compared with bread, butcher's meat, and some other vegetables, has been well ascertained to be in the following proportions:—

100 lb. of pease contains of nourishing matter,	93 lb.
seed of Haricot kidney-beans, . . .	92 ”
seed of garden-beans, . . .	89 ”
wheaten bread, . . .	80 ”
average of butcher's meat, . . .	35 ”
potatoes, . . .	25 ”
carrots, . . .	14 ”
cabbages and turnips, . . .	8 ”

The composition of the field-pea is thus given by Mr Stephens, in “*Book of the Farm*,” and as little difference, if any, can exist between these and the garden varieties, it may be taken as a close approximation to the truth—

*Pea-Ash.—Mean of four analyses.*

Potash, . . . . .	36.05
Soda, . . . . .	7.42
Lime, . . . . .	5.29
Magnesia, . . . . .	8.46
Oxide of iron, . . . . .	0.99
Phosphoric acid, . . . . .	33.29
Sulphuric acid, . . . . .	4.36
Chlorine, . . . . .	—
Silica, . . . . .	0.51
Chloride of sodium—common salt, . . . . .	3.13
	99.50

The chemical composition of pease, Mr Stephens observes, has not yet been carefully investigated. Let this statement suffice—

Composition of the Grain.			Composition of the Meal.		
Water.	Husk.	Meal.	Starch.	Legumin.	Gum, &c.
14.0	10.5	75.5	65.0	23	12

*The inorganic constituents in the pea—*

100,000 parts of seed contain 2464, and 100,000 parts of the straw contain 4971 parts of inorganic matter, consisting of—

	Seed.	Straw.
Potash, . . . . .	810	235
Soda, . . . . .	739	—
Lime, . . . . .	58	2730
Magnesia, . . . . .	136	342
Alumina, . . . . .	20	60
Oxide of iron, . . . . .	10	20
Oxide of manganese, . . . . .	—	7
Silica, . . . . .	410	996

Phosphoric acid, . . . . .	190	240
Chlorine, . . . . .	38	4
—SPRENGEL.	2464	4971

The per-centage of mineral ingredients taken from the soil is computed to be—pod, from 2.5 to 3; 7.1 husk; 4.3 to 6.2 straw.

## § 2.—THE BEAN.

*Natural history.*—The garden or broad bean (*Vicia Faba L., Faba Tou., vulgaria Moen.*) belongs to the natural order Leguminosæ, subdivision Sarcobolæ, tribe Viciæ, and to the class Diadelphæa, and order Decandria, in the Linnæan arrangement. The genus *Faba* contains only two species—the common garden-bean and the horse-bean, *F. equina*. The name *Faba* is derived, according to Isidorus, from *phago*, to eat; according to Martinius, from *paba*, to feed; while others will have it from *haba*—all of which are modifications of each other. The origin, however, is evidently Greek.

That the East, and probably Egypt, is the native country of the bean, is pretty generally admitted. This appears to be the most ancient of all our now cultivated esculents. The earliest notice we have of the bean is of those brought by the three loyal Israelites who followed King David, and presented him with beans when he fled across the Jordan from his rebellious son Absalom. One of the noblest families of Rome, the Fabii, derived its name from a circumstance connected with this plant. The Athenians used sodden beans in their feasts to Apollo. The Romans had a solemn feast called *Fabaria*, at which they offered beans in honour of *Carna*, the wife of *Janus*, whose palate, according to *Lemprière*, was gratified by the addition of bacon; hence the origin of bacon and beans is of far older standing than modern chawbacons suppose. *Pythagoras* enjoined his followers to abstain from beans, professing to believe that at the creation man was formed of them. The Romans believed at one time that the souls of such as had died resided in beans. *Clemens Alexandrinus*, *Theophrastus*, and even *Cicero*, entertained equally extravagant notions of them. The Egyptian priests held it a crime even to look at beans. The *Flamen Dialis* was not permitted to mention the name; and *Lucian* introduces a philosopher in hell saying, that to eat beans and to eat our father's head were equal crimes. A more rational use is stated by

*Philips* to have been made of them by the ancients, namely, "in gathering the votes of the people, and for electing the magistrates: a white bean signifying absolution, and a black one condemnation;" and hence he supposes the practice was derived of black-balling obnoxious persons. Beans grew wild in Morocco in *Pliny's* time; and he says some were so tough and hard that they could not be boiled tender. This is confirmed by the circumstance of one of our now most popular sorts, the *Mazagan*, having been introduced to us from a place of that name on the coast of Morocco.

At what period the first beans were introduced to Britain is not now known. It must, however, have been at a very early period. Some suppose they were introduced by the Romans: we can hardly suppose this, as they could not have been in any variety, which is tantamount to their not having been extensively grown, in *Gerard's* time, who says the garden-bean is the same as the field one, only improved by cultivation. One peculiarity in the bean is worth noting: the ancient authors mention only one bean, and *Gerard* appears only to have known two; and even at this day, they have not multiplied in varieties to any extent like the pea.

*Use.*—The garden-bean is much less in estimation amongst the higher classes than the pea; and hence a much less proportionate breadth of it is required in first-class gardens than in those of less pretensions. It is, and always has been, the vegetable of the lower and middle classes, more used in England amongst them than in Scotland and Ireland, and by no means at all common on the Continent, even in vegetarian communities. It is used in its young state, in which state only it should be employed, as an article of luxury: the want of attention to this is one of the chief causes why it so seldom appears upon tables polite. Amongst the peasantry it is used in its full grown state, as an accompaniment to bacon. The white-blossomed bean, if gathered while quite young, makes an excellent dish, particularly if served with bacon or ham. The lower classes use them when full grown, at which time, although nutritious for strong constitutions, they are very unfit for persons of delicate digestion—for they are, particularly the inner skin, exceedingly indigestible.

*Columella* notices them, in his day, as food for the peasants only:—

"And herbs they mix with beans, for vulgar fare."

An English poet somewhere says, in allusion to the same,—

"And give them beans and bacon, till they burst."

It was a prevailing opinion among the ancients that beans were flatulent; and *Hoffman* and others among modern physicians assert the same; and not only that, but that the greener they are, the more they are so. *Dr James* says young beans are both a wholesome and nutritious food; but the now prevailing opinion is, that they are a flatulent and coarse food, better suited to the hard-working husbandman than to those of sedentary habits. *Boyle*, to ascertain the amount of air they afford—for on this their flatulency depends—treated them pneu-

matically, and found that the expansion of a single bean while growing is capable of raising a plug loaded with one hundred pounds' weight. The beans are the usual part of the plant used as food; but Philips informs us that the green pods, boiled after the beans are removed, is a dish that many people prefer to the beans themselves, and that the pods should be served with parsley and butter, as boiled beans usually are. He adds also, that the young beans, boiled in broth, are esteemed highly emollient. Par-boiled beans, boiled in a weak syrup of honey and musk, make an excellent bait for fish.

*Propagation.*—All the bean tribe, being annuals, are propagated by seed.

*Planting.*—Crops to come in earliest in the succeeding season are sown or planted (for beans are said to be planted, and not sown, as they are set at a greater distance from each other than pease and similar crops that are set thicker or sown) in the latter end of October, in November, December, January, and so on till May, sown after which they would scarcely come to perfection. Once a month for the early crops, and once a fortnight for the two general crops, is sufficiently frequent, few even sowing above three or four crops at most during the season. These periods apply to the open borders. They are also sown after the manner of pease (*which see*), under cover, and transplanted, as will be noticed below. Beans planted in March are fit for gathering in June, and ripen their seed in July.

The ground having been prepared by trenching or deep-digging, and well manured, drills are opened with the hoe (as has been described for pease) 3 inches deep; the drills for the Mazagan bean, which, on account of its hardness, is preferred for autumnal planting, should be  $2\frac{1}{2}$  feet apart, the beans being set in the lines 3 inches distant from each other; the soil is drawn over them with the hoe or a coarse rake, and left quite rough on the surface. Finely raking the ground over such crops is an absurdity, but old habits are difficult to set aside. The opener the soil is left, the better it excludes frost; the smoother it is made, the more likely is it to cake, and become, in some soils, so hard that, were the beans not possessed of the extraordinary expansive power stated by Boyle, and noticed above, they could hardly force their way through it. True it is that the crust might be broken by drawing the rake over it,

but in this operation there would be a great chance of breaking the necks of the beans at the same time. A crop of lettuce or early cabbage may be planted between the rows, either of which would come off while young, for use, before the beans arrive at a height to injure them. This is the practice of the London market-gardeners. We should here, however, state, for the information of that class of gardeners who think a cabbage is unfit for use until it be as hard as a cannon-ball, and almost as large as a drum, that early cabbage is in most estimation when quite young and tender, and just before they begin to turn in their leaves, or form a solid heart. This is an eligible situation for such a secondary crop, as the first planting of beans should be made on a warm well-exposed border. The same precautions will be required to save the crop from mice and other enemies as are recommended for pease. In cold damp soils and late situations, the rows of beans at planting may be covered with 2 inches of finely-sifted coal-ashes, rotten tan, or the like; either will exclude frost and counteract damp. Not, however, that frost is to be dreaded, for the bean will bear a considerable amount of it; but the principal intention is to keep the soil dry and prevent the escape of heat which it has absorbed during summer, and with which it has not by the end of October altogether parted.

In planting the secondary and principal crops, more open situations should be chosen; and for them it is important that the ground be moderately enriched, and trenched at least 2 feet in depth. Trenching is an assistant to manure; in some cases it is even more than a substitute. In regard to distance, that depends, as has been shown in the case of pease, mainly on the sort of bean to be planted, and the height it is to attain. The new royal dwarf cluster is 1 foot in height; a distance of 18 or 20 inches should be given, as it branches out close to the ground—and even at that distance, in good ground, will nearly cover the whole surface. For the white blossomed, which attains the height of from 3 to 4 feet, that space, or rather more, should be allowed. Marshall's early prolific is about 18 or 20 inches high; give it, therefore, a proportionate distance. Almost all the

rest, with the exception of the dwarf tan or bog bean, which is not worth notice, grow about 3 feet or more in height: they require, therefore, the largest space; and as has been, we hope, clearly enough stated in the case of pease, that there is great loss in crowding such crops, we would advise 4 feet apart for each of these. Regarding distance plant from plant, the new royal cluster branches out, forming a dense bush crowded with pods; it should be planted a foot apart in the line, and the seed placed  $2\frac{1}{2}$  inches deep; the white blossomed should be placed 3 inches apart in the line; Marshall's prolific as much, as it is a branching one to some extent, and the same depth as the last: the rest should not be nearer than 4 inches in the line, and all of them  $3\frac{1}{2}$  inches deep.

Beans forwarded for transplanting, as has been recommended for pease, should, as soon as they are 4 inches high, if the weather be favourable, be brought out and set in their permanent place. For this the best way is to stretch a line from end to end of the ground in a south and north direction (for reason, *vide* PEA). The surface is then smoothed down along the line, and a trench taken out with a spade, as in planting box-edgings, and to the depth of 5 inches, so that the roots may be the better arranged. Along the line set the plants at distances apart according to their kinds as specified above, taking them carefully out of the pots or boxes they have been growing in, separating them so that their roots receive no injury; cover the roots carefully, and proceed with the next row in like manner, pointing over the ground as the operation proceeds, and leaving it as rough as possible. A few branches of any deciduous tree should be stuck along each row, on the side the prevailing winds of the season blow from, avoiding evergreens, as, while they no doubt shelter the plants best, they are apt to become blown about by the wind themselves, and may do more harm than good. The wire cages we have spoken of in the article PEA will be found exceedingly useful for setting over the newly-planted beans, and to them a few branches of evergreens might be firmly tied. This would prevent their being blown about, and afford a much more efficient protection at the same

time. Of all modes of protecting such crops, short of glass-cases, we believe there is none better than this. From the distances we have given, there will be no difficulty in calculating the quantity of seed required. The following is Abercromby's allowance, and his, as he was so minute in such matters, may be taken as the greater quantity—we, since his day, planting much thinner: For early crops, one pint of seed for every 80 feet of row; for general crops, two quarts for every 240 feet; and for late crops, nearly the same as for the early ones. This is presuming the smaller kinds to be employed. In summer, it often happens that the ground is too dry to promote speedy germination in seeds so dry and hard as the bean. Some have recommended, in this case, steeping the beans for an hour or two in rain-water previous to planting. A much better way is to soak the ground with water as soon as the drills are formed, to plant the seed, and cover up immediately. Virgil says that soaking beans in lees, or dregs of oil and nitre, has the effect of causing a more rapid vegetation, and the production of a larger crop; and other ancient authors recommend their being steeped for three days in water mixed with urine.

It is a common practice in cottage-gardening economy to plant beans along with crops of potatoes, and also with cabbage, setting a bean between every two plants in the line. Speechley, in "Practical Hints," p. 17, recommended this, and brought forward his beans first in a bed thickly sown, and in a warm place—when of a fit size transplanting them, setting a bean alternately with a potato or cabbage in the same row; but in such cases he had his rows 3 feet apart, and his potatoes 18 inches apart, so that the bean is 9 inches from the potato on each side. Being advanced somewhat before planting, the beans have the start of the potatoes, and are matured and removed before they injure the potato crop. The propriety of this mode has been questioned; but we have seen excellent crops of both vegetables so produced. In garden-culture the process of transplanting beans is very advantageous: it moderates their growth, so that they do not incline to increase in height after their flowers are set, and induces precocity in the maturing of the crop.

Instead of planting in continuous lines, a good way is to plant in detached patches of four or five seeds each, at distances agreeable to those given above.

*Subsequent cultivation.*—Beans, like all other crops, require to be kept clear of weeds, and to have the soil well stirred up between the rows during their growing season. When they have attained the height of 6 inches, it is proper to draw a little earth to the stems, merely to keep them steady, as the bean is not disposed to send out horizontal roots so near the surface as to derive any advantage from the soil thus gathered round them. Nor is it a usual practice to afford them any support, as in the case of the pea, although no valid reason can be given to the contrary. True, the bean is not a tendrilled climbing-plant like the pea, and hence could not attach itself to the supports presented to it; but we have seen the tall-growing sorts so often beaten down by strong winds, even in not very exposed places, that we often do, in defiance of usual practice, support them when in lines, by driving in, along the rows, stout stakes, 6 or 8 feet asunder, and running a line of tarred cord along both sides of the plants, at the distance of about 15 inches apart, the first one being that distance from the ground. Those grown in patches, as above, have three stakes to each, with two tiers of cord as above.

When the plants are fully in bloom, or rather when they have set their flowers, and the first series of beans have made two inches in growth, three inches of the tops of the plants should be pinched off, to throw that nourishment which would be expended in uselessly increasing the height of the plant into its general system, and consequently increase the bulk of crop, as well as advance its early maturity. This often-recommended operation, although disregarded by many, is of very signal importance. Some, to secure a very late crop, cut over a few rows of a progressing one just when the plants are in full flower. New shoots are formed at the bottom of the stem, which shoot up and produce a crop late in autumn. Did it not occur to him who first recommended this, that, by sowing a crop later in the season than general crops usually are, the same end would be arrived at, and in a far more business-like manner?

In gathering the crop, the first attack should be made on them when the beans are about the size of a marrow-fat pea. In such state only are they fit for a table where elegance in display and gastronomic taste are cared for. A disregard of this on the part of the purveyor has probably tended more than anything else to banish this excellent esculent from the tables of the great. The young gardener should attend to this; and, indeed, the same rule is applicable to every other article of garden produce. He may rest assured that his success in life depends to a great degree on the quality of his productions, not altogether on the quantity; and he may set it down as a pretty general rule, that all vegetables are most appreciated when young and delicate: and to none does this more strongly apply than to the Order of which we are now treating.

*Soil and manures.*—In a strong aluminous soil the bean luxuriates most; that soil must, however, be rich, and highly cultivated. In light soils they are earlier, but their produce is less, nor do they continue so long in bearing. It is the force of manure and high cultivation that enables the gardener to produce good crops of this plant when he has to contend with a light and gravelly soil. In soils of the latter description, it is scarcely possible to manure too highly; and of all fertilisers, that of the stable or cow yard is the best in such a case. Mr Stephens, in the "Book of the Farm" (vol. ii. p. 423), gives an excellent instance of the beneficial effects of *gypsum* being used as a top-dressing to an acre of beans, and that at the very moderate cost of 6s., the quantity applied being 4 cwt. The balance in produce in favour of one acre so treated over another that received no top-dressing, was  $11\frac{1}{2}$  bushels of beans and 127 stones of straw, the cash profit in the one case over the other being £3, 4s. 4d. No other manure was used; the ground was, however, dressed with  $2\frac{3}{4}$  chaldrons of quicklime slaked in water, that held common salt in solution in the proportion of 1 cwt. to the chaldron of lime, before the beans were sown on the 6th of March. The top-dressing was applied on the 6th of May, and the crop reaped on the 1st of September. The soil was partly moss, partly sand or gravelly loam, and had been trenched 16 inches deep, and

well incorporated together. This is an interesting case to the gardener, supposing him to have the eighth of an acre under beans, which would be in his case a considerable breadth. He could, at the above rate, produce his crop at a cost of 1s. 6d. for manure; for we hold the previous lime-dressing, stated above, to have had immeasurably less effect on the crop than the already fertile state of ordinary garden-ground would. Another instance of the effect of a combination of special manures is given by the same accurate authority in the paragraph following that from which the above statement is taken:—2 cwt. animal charcoal (1 cwt. dissolved in sulphuric acid), 56 lb. sulphate of magnesia, 2 cwt. common salt, 1 cwt. nitrate of soda, at a cost of £1, 7s. 10d., used as a top-dressing to an acre of beans, produced 11½ bushels of beans, and 146 stones of straw, beyond that of an acre of the same kind of crop which was not top-dressed at all, leaving a cash profit of £1, 7s. 1d. in favour of the top-dressed acre. In this latter case the soil was a stiff loam resting on red sandstone. The top-dressing was applied on the 21st of May, and the crop reaped on the 8th of October.

“Soluble manures, such as the nitrate and sulphate of soda and potash, and dissolved bones, are most commonly applied to the bean crop, in the form of top-dressings, after the plants have made considerable progress above ground; and they can readily be brought within reach of the roots, and mixed with the soil, during the operations of hoeing. Gypsum and lime, as both of them require a long time for solution, should undoubtedly be applied to the land before sowing the seed. Gypsum may be very advantageously applied when sowing the seed, either in contact with it, or so near as to be within immediate reach of the roots. Common lime, in the caustic state, when laid on as manure for beans, does best when this operation is performed when preparing the land for the winter furrow. The organic composition of the straw and grain of beans, as determined by analysis, exhibits a larger amount of nitrogen than is to be found ‘in any of the cultivated cerealia.’ This fact proves the necessity for a soil being rich in decayed animal and vegetable matter, as well as in those

mineral substances already spoken of. Organic manures must, however, be viewed only as subsidiary, in the cultivation of beans, to the more important mineral substances already referred to. Fortunately the two most important organic manures (farmyard dung and guano) also contain important mineral matters. Farmyard manure is undoubtedly our best manure for beans, as it is for most other crops; yet its action can be greatly enhanced by the addition of purely mineral substances, because by the combination we supply all that is necessary for perfecting every part of the plant. Guano is rich in nitrogen (ammonia), but greatly deficient in alkaline mineral matter. Hence, when applied as a manure for beans, on soils different in potash and soda, its action is frequently feeble and unsatisfactory. On soils rich in vegetable matter,” as almost all garden soils are, “it is advisable to use mineral manures, such as lime, magnesia, potash, and soda, either in one form or another; while on those that are deficient in decaying vegetable and animal matter, but abundantly supplied with mineral substances, an application of farmyard manure or guano would be preferable. While pointing out certain special manures as peculiarly adapted, by their composition, to the growth of beans, it should ever be kept in view, that the true art of cultivation consists in making the land support itself as much as possible; and this, on all soils of a medium character, or above it, can in a great measure be effected, irrespective of extraneous manures, by improving their physical condition, and eliminating, by deep and thorough cultivation, those stores of nutritious matters, which otherwise would remain locked up and unavailable. A thorough stirring, pulverisation, and clearing of the soil, during the growth of the bean crop, or indeed of any other crop whatsoever, is equivalent, and frequently superior, to adding a certain amount of manure where these operations are neglected, or performed in an inefficient manner; because, by the admission of air, oxygen, carbonic acid, and water, the great solvents of all mineral and vegetable matter contained in the soil are thus allowed to exert their peculiar action upon what would otherwise remain inert.”

—MORTON'S *Cyclopedia of Agriculture*.

Sulphate of soda, and most other mineral manures, can only be beneficially applied to land in good condition and in careful hands, because if the land is poor, they will have no effect whatever. The stableyard manure-heap must ever be regarded as furnishing the principal part of the food of plants. What are called special manures are only the condiments, like pepper, salt, mustard, and the other contents of the cruet-stand.

*Forcing.*—The garden bean is not considered of sufficient importance to be ever forced in this country; if it were so, what has been said of pease under this head would be quite applicable to it.

*Taking the crop.*—Beans, to be eaten in proper condition, should be gathered young—indeed, when of the size of a large marrow-fat pea. They are gathered in succession, until the eye begins to turn black at the hilum or point of attachment to the pod, at which period they become exceedingly coarse food, flatulent, and indigestible.

*Approved sorts and their qualities.*—1. *Early Mazagan.*—From 2 to 3 feet in height; the hardest sort in cultivation, although originally a native of Mazagan on the African coast; stems slender; by no means productive, the pods containing seldom more than four beans. Its hardness and precocity have secured it a place in our gardens for upwards of one hundred years. It is known as early Malta, early Aldridge, Stidolph's new early, and early Bromley. It is the *Fève de Mazagan* of the French. The weight of an average seed is about 15 grains, one pound containing 481 seeds.

2. *Marshall's early dwarf prolific.*—From 18 inches to 2 feet in height. This excellent bean originated about twenty years ago with Mr Marshall, a gardener, near Kingston, Surrey. It is fully a fortnight earlier than the *Mazagan*, much more productive, producing its pods in dense clusters near the ground; plant very much branched; beans larger than in the last, and producing from four to five in each pod. It is known as *Marshall's prolific*.

3. *Royal dwarf cluster.*—From 10 to 14 inches in height. Comparatively a new variety, the history of which is not very clearly known. We suspect, from its habit, that it is an accidental variety of dwarf habit of the last, or one of taller growth than the next. It produces its pods in clusters, three or four beans in each pod, which are smaller than the last. It branches considerably, and therefore should have not less than 10 or 12 inches in the line, which is nearly its proper distance between the rows. With *Marshall's prolific* it should have a place in every small garden. We grow it extensively on account of the delicacy and smallness of the beans while young.

4. *Dwarf fan.*—The smallest of all garden beans, seldom so tall as the last; pods small, round, containing in general three small oblong beans; pods produced in clusters close to the ground. Known also as the fan or hog, dwarf cluster, or bog bean. The *Fève naine hâtive* of the French. It is not in general cultivation, but is well suited for small gardens, yielding a moderate crop of well-flavoured beans. Seeds weighing from 19 to 20 grains.

5. *White blossomed.*—From 3 to 4 feet high; the most delicate flavoured of all beans, but by no means productive; pods long, nearly cylindrical, containing seldom more than four beans, which, when ripe, are of a blackish colour. Flowers white, unlike any of the family. It is known also as the white-blossomed long pod. An average-sized seed weighs  $1\frac{1}{2}$  grains; the smallest seeded of all the garden sorts.

6. *Long pod.*—From 3 to 4 feet in height; pods long and narrow, containing in general four beans of excellent quality. A most productive variety, and generally employed for the summer crops. One of the most popular of all the family, and has been long in cultivation, which accounts for the following synonyms. *Lisbon*, early *Lisbon*, *Sandwich*, *Windsor long pod*, *Turkey long pod*, *common long pod*, *early long pod*, *large long pod*, *hang-down long pod*, *sword long pod*, *moon*, *Wrenche's early moon*. To which *Johnston's wonderful may*, for all useful purposes, be added, as it differs only in the greater length of the pods, and slightly flatter form of the bean.

7. *Dutch long pod.*—From 3 to 4 feet high. An abundant bearer; will succeed the long pod even if sown on the same day. Pods long and broad, containing, on an average, from four to six large flat white beans.

8. *Green long pod.*—From 3 to 4 feet in height. Pods long, somewhat flattened, containing in general four rather small oblong beans, an excellent bearer, and only a few days later than the long pod. Esteemed on account of the fine green colour of the beans, which, if gathered at a proper time, retain their green colour when dressed. Known also as the *green Genoa* and *green nonpareil*. It is the *Fève verte*, *Fève toujours verte*, of the French. The long pods weigh from  $2\frac{1}{2}$  to  $3\frac{1}{2}$  grains, the lightest being *Child's new early long pod*, and the heaviest *Sangster's imperial long pod*.

9. *Windsor.*—3 to 4 feet high, pods short but very broad, containing seldom more than two beans, which are very large, flat, roundish; esteemed excellent for a summer crop on account of their remaining longer fit for use than any other, excepting the *green Windsor*. Known also as *Wrenche's improved Windsor*, *new Windsor*, *Kentish Windsor*, *broad Windsor*, *Taylor's Windsor*, *Taylor's large Windsor*, *Taylor's improved new Windsor*, *Mumford*, and *small Spanish*. It is the *Fève de Windsor* of the French. Weight of seed, 47 grains (or  $\frac{1}{2}$  of an ounce nearly), being the heaviest seeded of all beans.

10. *Green Windsor.*—Very much resembling the last, only the beans remain green after they are ripe, and hence are thrust into the market

when most other beans are done. It is known as the Toker, and is the Fève de Windsor verte of the French. Weight of seed, 36 to 37 grains.

11. *Red Windsor*.—In character similar to the last two, differing, however, in the beans being of a light red colour while young, and dark red when ripe, which renders it seldom sought after. The French have a bean very similar, under the name of Fève violette. Weight of seed, 31½ grains.

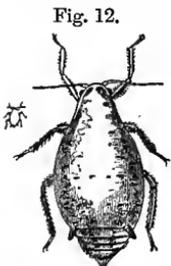

12. *Green China*.—From 2 to 2½ feet in height. Not much cultivated, but is deserving of greater notice on account of its productiveness and coming in late; pods long, cylindrical, containing three or four heans, which remain green when dry. Much cultivated on the Continent, and known as the Fève verte de la Chine.—*Bon. Jard.*, edit. 1835.

13. *Dwarf crimson seeded*.—Esteemed only on account of its earliness and dwarf habit, in both of which it exceeds all the other beans, seldom attaining a foot in height. Pods produced in great abundance, about 2 inches long, well filled with beans of a crimson colour, and nearly as large as the long pod. Known as Vilmorin's dwarf red seeded. This is the Fève très naine rouge, nain rouge, of the French.

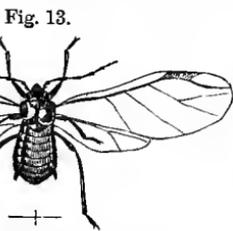

The varieties of beans have not increased by any means in the same ratio as pease, for which both cultivators and seedsmen ought to be thankful. As a selection from the above, we would recommend Nos. 2, 3, 6, 8, and 9; and No. 5, where delicacy of flavour, at the expense of a moderate return, is no object.

Gregory's early hang-down is merely seed selected from No. 6. The thick-seeded Windsor, Child's long pod, green long pod, Sangster's imperial long pod, green fau or cluster, and other names found in catalogues, are scarcely worth the attention of the cultivator.

*Insects and Diseases*.—The bean is liable, particularly in dry seasons, to the attacks of the *Aphis fabæ*, the black-fly collier, or, as it is in many places called, the dolphin. It is a species of plant-louse. It attacks the young stalks towards their tops, and the leaves also; and in a few days after their appearance, like all the Aphis family, it multiplies in prodigious numbers, rendering the top of the plants a mass of sooty blackness. Fig. 12 shows

WINGLESS FEMALE OF THE BEAN APHIS.

WINGED MALE OF THE BEAN APHIS.

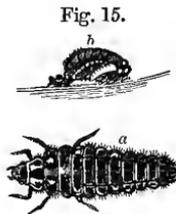

the female wingless insect; while fig. 13 exhibits the male. The ladybirds—of which there are two, the constant inhabitants of gardens, *Coccinella bipunctata*, fig. 14, a, the two-spotted ladybird, and *Coccinella septempunctata*, b, seven-spotted ladybird—are their greatest natural enemies, as they are to all the Aphis tribe. The grub of the ladybird is shown, fig. 15, a, and the chrysalis b.

LADYBIRDS.

They devour them in astonishing numbers; and therefore, for this service, and from being harmless themselves, they rank amongst those insects which should be protected with the greatest care.

The most ready means, and that generally followed, in ridding ourselves of the *Aphis fabæ*, is to cut off the affected tops, put them in a bag, and consign them to the nearest fire. It is useless to cut off the tops and leave them on the ground; for even the wingless females will soon reascend the plants, and the winged males speedily regain their former station. The operation of topping heans lessens greatly the multiplication of these insects, as it is the young and most tender leaves and tops that they prefer to attack. Dusting the plants with caustic lime in powder, tobacco juice and fumigation, Scotch snuff, sulphur, hellebore dusted over them in a state of powder, and a variety of other means, have been adopted, all having more or less effect;

GRUB AND CHRYSALIS OF THE LADYBIRD.

but topping is the radical cure after all. The humble-bee (*Bombus terrestris* L., and *B. lucorum*), works considerable damage to the bean crop, by perforating the flowers on the upper side of the calyx with its mandibles, and inserting its proboscis into the nectary to secure the honey contained therein. This operation is necessarily of great injury to the crop, as the majority of the flowers so probed are not able to perfect their seed.

SITONA CANINA.

Several species of the extensive genus *Sitona* (weevils) are often very destructive, not only to

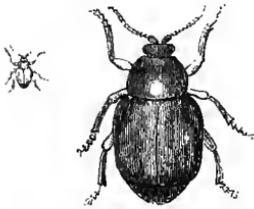

OTIORHYNCHUS PICIPES.

Several species of the extensive genus *Sitona* (weevils) are often very destructive, not only to

the bean, but to most of the order Leguminosæ. These are, *Sitona canina*, fig. 16; *S. lineata*, fig. 7, and *Otiorynchus picipes*, fig. 17. These attack the bean shortly after its appearance above ground, and continue to feed upon it during the whole progress of its growth. The same means must

Fig. 18.

YELLOW-FOOTED BEAN BEETLE.

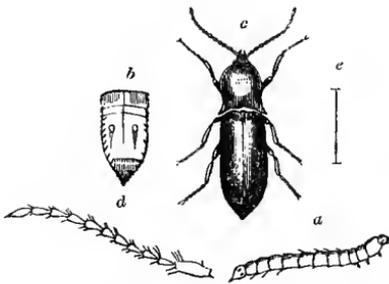

be applied as noticed above. The little beetles, *Bruchus granarius*, fig. 9, and *B. flavimanus*, fig. 18, deposit their eggs in the blossom, to prey afterwards on the ripe seeds.

A parasitic fungus (*Uredo fabæ*) abounds on the leaves of the bean

towards the latter end of summer. Its effects do not seem to be of great consequence; were it even so, sulphur applied as has been recently recommended for the destruction of mildew, will lessen, if not totally destroy, this parasite.

The wire-worm (*Cataphagus lineatus*, Linn.), fig. 19, belongs to the order Coleoptera, family Elateridæ. The perfect insect is about one-

Fig. 19.

a, WIRE-WORM; b, CAUDAL JOINT MAGNIFIED; c, PERFECT BEETLE; d, ANTENNA.

third of an inch in length, and is described by Stephens as being "fuscous, with a griseous pubescence. Head and thorax blackish, the latter with the lateral branches nearly straight, and the posterior angles very acute; the disc very convex, and thickly punctate; scutellum fuscous; elytra broad, a little attenuated, rounded at the apex, very convex; punctate striated; the striæ disposed in pairs, and united at the apex, griseous yellow, with the alternate narrowed interstices fuscous or dusky; margins and apex of the abdomen ferruginous; antennæ and legs rufo-testaceous; the femora sometimes dusky, rather variable in colour, being more or less pubescent or testaceous."

The true wire-worms are the produce of various species of click or skipping beetles, known as skipjacks and spring-beetles in parts of the country, or elaters, as—

*Elatér* (*Adrastus*) *acuminatus*, the acuminated click beetle.

*E. (Athous) longicollis*, the long-necked click-beetle.

*E. (Athous) niger*, the black click-beetle.

*E. (Agriotes) obscurus*, the obscure click-beetle.

*E. (Melanotus) fulvipes*, the tawny-legged click-beetle.

*E. (Lepidotus) holosericeus*, the satin-coated click-beetle.

*E. (Agriotes) sputator*, the spitting click-beetle.

*E. (Athous) ruficandis*, the red-tailed click-beetle.

*E. (Agrypnus) murinus*, the mouse-coloured click-beetle.

*E. (Dolopius) marginatus*, the margined click-beetle.

One of the natural enemies to these is the genera *Fileria*—slender worms, which live in wire-worms. Another is *Steropus madidus*, a ground-beetle or carabus, which feeds on them.

The millipedes and maggots of gnats are erroneously called wire-worms; they are, however, destructive in their way. They belong to the genus *Iulus*.

*I. Londonensis*, the London snake millipede.

*I. pilosus*, the hairy snake millipede.

*I. pulchellus*, the beautiful snake millipede.

*I. punctatus*, the dotted snake millipede.

*I. terrestris*, the earth snake millipede.

*I. latostriatus*, the broad-lined snake millipede.

The larvæ of the Elater are of a yellowish-brown colour, slender, flat, smooth, and shining, slightly pubescent, resembling the meal-worm; the body, exclusive of the head, is composed of twelve scaly rings, the last of which is not notched at the tip, as is the case with some of the species; it has six very short legs, they have a series of spirals on either side; the under side of the end segment has a fleshy tubercle, employed as a leg, and, when not in use, concealed at the base of the segment. It remains five years in the grub state, in which it is most injurious, and commits great devastation among florists' flowers. These grubs are exceedingly destructive to carrots, potatoes, turnips, cabbages, &c.; we have not unfrequently lost crops of beans also by them. Various have been the means employed to effect their destruction; the most simple, and probably the most effectual, is to place slices of potatoes on the point of a stick, and bury them about two or three inches under the surface, which should be examined every day, and the wire-worms collected and burned. By these means we succeeded in capturing in a border of carnations no less than 6360 at three takings. The number of traps set was 106, and the average number of wire-worms per trap was 20: at one taking we captured 2120. By persevering in this manner for about a fortnight, examining the traps every third day, we so completely cleared the border, that it has been kept stocked with carnations for the last four years, and now we do no lose a plant. Some prefer laying the slices of potatoes on the surface of the ground, as also slices of turnip, and portions of lettuce-stalks, to which the worms are attracted, and may be collected in great numbers. Some recommend turning up the soil frequently, to expose them to the attacks of birds. Pheasants destroy them in vast numbers, but we are not certain but they do more harm in other ways

than good in this. Rooks and moles are also very serviceable in keeping down this pest of the garden and the field. Spirit of tar, dug into the ground, at the rate of 1 gallon to 50 square yards, has been with us a satisfactory remedy; and to render the liquid more divisible, we absorb it in dry sand, or dry finely-sifted coals, and then sow the ground with it. The refuse lime of gas-works, which contains in general a considerable amount of impure sulphuret of lime, or lime combined loosely with sulphuretted hydrogen—a gas the most deleterious of all others to animal life—has been employed with singular effect also. The mole lives chiefly on the wire-worm for a great portion of the year. In cold wet seasons the wire-worm is most destructive. And, in fact, where ground is overrun with wire-worm, it is not a bad way of clearing it, to sow old seed of beans in drills, and to take them up after the first week once every two or three days, when the beans will be found thickly perforated by the insects, which may be destroyed and the beans re-sown again.

The gamma moth (*Plusia gamma* of some naturalists, *Noctua gamma* of others), fig. 20.

Fig. 20.

THE GAMMA' MOTH.

This very pretty moth may be described as having beautiful glossy greyish-coloured upper wings, marbled with brown, having a slight metallic shade; about the middle of each is a gold shining mark, resembling the Greek letter  $\gamma$ , from which circumstance it derives its name; the under wings are of a pale ash-colour with a brown edge; the head and collar purplish-brown, margined with grey lines; abdomen yellowish-grey, having elevated tufts of hairs.

The caterpillar is green, with several short single hairs interspersed over it; four small whitish-yellow lines down its back, and a broad yellow stripe along each side; head brownish green; furnished with twelve feet—two behind, four abdominal, and six fore-feet. The female deposits her eggs, which are hemispherical, on the under sides of the leaves, in a somewhat regular manner; they are said to lay four hundred of these eggs at a time.

These caterpillars are found pretty abundant during the summer, feeding on lettuce, beans, pease, and even wormwood, thistles, and sage. They made considerable ravages in France in the year 1735, according to Reaumur, during the month of July, eating up all the leguminous vegetables, leaving nothing but the stalks. They are found all over Europe, in Siberia, China, and North America. They first make their appear-

ance about April, and continue in full vigour till October, when they deposit their eggs, which are hatched at various times from May to September, but chiefly during July. These caterpillars commit sad havoc in the south of England; rarely, however, in Scotland, where they are only found troublesome in dry warm summers. There are four generations of moths during the season, and when we consider that a single pair can produce 80,000 eggs, which, barring accident, might become the progenitors of 16,000,000 of caterpillars in little more than twelve months, it is wonderful that they do not injure our gardens more than they usually do. Their attacks are pretty general, but, with the exception of lentils, they seem to prefer leguminous plants. The only means of subduing them appears to be capturing the insect in its moth state, hand-picking the caterpillars, or, as recommended for other insects which drop either from fear or from concussion, shaking the crop smartly, and receiving the caterpillars in a cloth spread along both sides of the rows. If merely shaken off, they would soon reascend the plant and renew their attacks upon it.

*General remarks.*—The European names of the garden-bean are—*boon*, Dutch; *jawa*, Italian; *fève de marais*, French; *alber janas*, Spanish; and *grosse bohne*, German.

Where saving seed is an object, a row or two, according to their length, and the quantity of seed required, should be left ungathered; for it is a bad way to gather the best of the crop, and to save the last formed, and consequently the weakest and worst, for seed; a sure way to deteriorate the quality of the sort, and render a variety that a long succession of years' careful cultivating and selecting has been spent in producing, worthless, by the mismanagement of one season. Even then only the finest pods should be saved; and to prevent accident, the crop should be gone over just as the pods are fully swelled, and all the smallest removed. This will throw additional strength into the pods left for seed, and insure a pure stock. Beans, like pease, keep best in the straw, therefore they should, when properly winnowed, be laid up in bundles, and placed in a dry airy loft. The seeds will retain their vitality longer than the pea, and if well kept, will grow after four or five years.

*The inorganic constituents of the bean are*—100,000 parts of seed contain 2136, and 100,000 parts of the straw contain 3121 parts of inorganic matter, consisting of:—

	Seed.	Straw.
Potash . . . . .	415	1656
Soda . . . . .	816	50
Lime . . . . .	165	624
Magnesia . . . . .	158	209
Alumina . . . . .	34	10
Oxide of iron . . . . .	—	7
Oxide of manganese . . . . .	—	5
Silica . . . . .	126	220
Sulphuric acid . . . . .	89	34
Phosphoric acid . . . . .	292	226
Chlorine . . . . .	41	80

—SPRANGEL.

2136 3121

The composition of the bean is thus given in "The Book of the Farm," vol. i. p. 1300:—

	Bean-ash.
	Mean of three analyses.
Potash . . . . .	33.56
Soda . . . . .	10.60
Lime . . . . .	5.77
Magnesia . . . . .	7.99
Oxide of iron . . . . .	0.56
Phosphoric acid . . . . .	37.57
Sulphuric acid . . . . .	1.00
Chlorine . . . . .	0.73
Silica . . . . .	1.15
	98.93

One quart of Mazagan beans (one of the smallest sized) contains 434 beans, and one quart of Windsor (one of the largest) contains 179 beans.

### § 3.—THE KIDNEY OR FRENCH BEAN.

*Natural history.*—The kidney or French bean (*Phaseolus vulgaris*, L.) belongs to the natural order Leguminosæ, subdivision Sarcobolæ, tribe Phaseolæ; and to the class Diadelphia, and order Decandria, in the Linnæan arrangement. The genus *Phaseolus* contains 14 species of plants cultivated for the food of man, exclusive of the species multiflorus, which forms the next section. Of *P. vulgaris* there are many varieties in cultivation, but, like those of pease, they are at present in considerable confusion as to identity. The name *Phaseolus* is derived from *Phaselus*, a little boat, from the resemblance in its seed-pods.

The kidney bean is a native of India, introduced to Britain before 1597—some say so early as 1509, and that it was imported from the Netherlands, about which period gardening began to be attended to in England, the white kidney bean being the first variety known in this country. Phillips, in "History of Cultivated Vegetables," vol. i. p. 74, says, "this pulse is generally but improperly called French bean, for its old French name, *Pève de Rome*, evidently proves it not to have been a native of France. We also find that it was called the Roman bean in our language about the time of Queen Elizabeth. Gerard also gives it the name of *Speragebean*, and says it is called *Faselles*, or long peason. The Dutch at that time (1596) called them *Turck's-boone*—that is, Turk's-bean. From these facts, but more particularly from the account of the great Roman naturalist, we may conclude that this wholesome and excellent vegetable is a native of the eastern extremity of Europe, or that part of Asia now belonging to the Turks; for Pliny, in the 7th chap. of his 18th book, mentions these beans, and says those of *Sesame* and *Iris* are red, resembling blood. He also, in his 12th chap. of the same book, calls them *Phaseoli*, and says the pod is to be eaten with the seed. From this laconic notice we may assume they were but little esteemed at that time in Italy, where lupins were then so much admired for food. The French name of *Haricot* originated from their being much used by cooks in the composition of a dish so called. The English name of *Kidney bean* was given on account of the seed being somewhat of a kidney shape. Gerard mentions a consider-

able variety that was cultivated in England in his time, and says, "The fruit and pods of kidney beans, boyled together before they be ripe, and buttered, and so eaten with their pods, are exceedingly delicate meate, and do not engender winde as the other pulse doe."

Kidney beans are amongst the most valuable of culinary vegetables, yielding a large return of crop, and continuing in use during the whole summer. The variety known as the scarlet-runner is a most productive sort, and although requiring the support of stakes in the manner of pease, yet it well repays the expense and the space it occupies. In Scotland this excellent vegetable is much less cultivated than in England; indeed, the cottager, and even many of a higher grade, do not appear to be aware of their merits. It is found in most cottage-gardens in the south, and made to add to the ornament of the garden, as well as used for culinary purposes. Philip Miller appears to have brought it into use as an article of food, for, prior to his time, we find it described as an ornamental annual, and placed in the flower border, and its flowers greatly sought after by ladies, to be put in their nosegays and cut-flower pots. The dried seeds of all the tribe are exceedingly nutritious as an article of food, constituting the *haricot* so much used on the Continent; indeed, the quantity of gluten contained in them nearly approaches that in wheat.

*Uses.*—Kidney beans, in their young state, are preserved in salt for winter use; they are also preserved as a pickle by themselves, and form an ingredient in mixed pickles. They are also used throughout the whole year as a legumen, and, being impatient of frost, a supply is kept up during winter and spring by growing them in hothouses. As an article of vegetable food, they are considered exceedingly wholesome, and much less flatulent than vegetables usually are. The ripe seeds are much used on the Continent in cooking under the name of *haricots*, which, as dishes, are as numerous as curries in Calcutta. For this purpose, the ripe seeds are steeped a few hours in water, which swells them out, and causes the outer skin to separate freely from the seed. In this state they are nutritious, when simply boiled, and served up to be eaten with other meats, but much less palatable than when they have passed through the hands of a skilful cook. *Haricots* are much in use in Roman Catholic countries, forming the greater part of the food of the people during Lent. The ripened seeds also enter into a variety of soups and stews. As an article of domestic economy, they are by far too little attended to; their produce is large; their cultivation during summer simple, and, in their green state, few vegetables are easier cooked. According to the analysis of Einhoff, 3840 parts of kidney bean afforded 1805 parts of matter analogous to starch, 857 of vegetable matter, and 779 parts of mucilage—clearly showing that it is the most nutritious of all legumens.

*Propagation.*—The whole of the dwarf varieties—that is, of *Phaseolus vulgaris*—

are to be regarded as annuals in this country, and consequently originated from seed.

*Sowing.*—The kidney bean, being a native of India, is consequently a tender plant in Britain; therefore sowing in the open air, even under the most favourable circumstances, cannot be safely recommended before the beginning of April for England, and even then in dry light soils and warm places. The latter end of that month is sufficiently early for Scotland. After the first sowing, to keep up a proper succession during summer and autumn, other sowings should be made in May, June, and July. In cold situations, and in strong cold soils, it will be advisable to sow the seed in a prepared bed, in boxes or in pots, in light rich soil, and when the plants are about 4 inches high, to transplant them into their final spot. They bear transplanting well; and the process recommended in the case of pease is applicable to them also. To keep up a supply during winter, the process of sowing should commence about the middle of October, and be followed up every fortnight till the middle of March.

For early crops in the open air, a well-sheltered border with a southern exposure should be chosen, the ground thoroughly pulverised, and if not in high manurial condition, it should be made so by additions of semi-decomposed stable-yard manure dug in previous to sowing. (For special manures, *vide* GARDEN BEAN, those recommended for it being applicable here also). The drills should be drawn across the border 2 feet apart, and about  $1\frac{1}{2}$  inch in depth; the seed should be set by the hand singly from 2 to 3 inches apart, according to the size of the variety, which distances apply to all the dwarf sorts, or kidney beans proper. The seed is sold by the pint, half a pint being sufficient to plant a drill 80 feet in length. It is very important that the drill be dry at the time of planting thus early, for, what with cold and excess of damp, the beans are very liable to rot as soon as they are buried in the ground. In sowing for transplanting, the seeds may be set as close to each other as nearly to touch; and, indeed, it is a good plan to sow one seed in a small 60-sized pot, and when 3 inches high, if the weather be favourable, to plant them

out with the ball entire. Even for secondary crops a warm spot is required; the distance as given above will be quite sufficient. We have, in general, found transplanting the first and second crops the most certain way of securing them early; and, indeed, for the former, have found much advantage by setting the lines from east to west, and placing along the northern side of each line a boarding 18 inches in height, which places the crop almost in the same condition as if it were planted at the bottom of a south wall, which seldom can be done with safety to the roots of the fruit-trees growing against it. The wire protecting-cages, alluded to in article GARDEN BEAN, will be valuable in the case of the first and second crops of kidney beans; and indeed the triangular case with glass on one or both sides, described in article PEA, might be used with the greatest advantage in this case also.

*Subsequent culture.*—Top-dressing, should the plants appear weakly, with any of the special manures noticed in article GARDEN BEAN, in either a dry or dissolved state—the latter being much more instantaneous in its effects—keeping the ground clear of weeds, and frequently and deeply stirring the soil between the rows, constitute the essentials of good cultivation. Some of the taller-growing sorts, if the soil be rich, and the season mild and humid, will require topping—that is, merely cutting off those straggling top-shoots that, under such circumstances, often spindle up and rob the crop of much of its food, as well as causing an undue shade upon it.

*Soil and manure.*—A much lighter and more thoroughly pulverised soil is required for the kidney bean than for the garden bean, and where it is naturally strong the crop will be much improved, if sown or planted in light vegetable mould, placed in drills drawn 6 inches deep for its reception: this will give the crop a fair start; and deep hoeing through the summer, leaving the surface rough, will admit the heat of the sun, of which this crop, being of tropical origin, stands in need in our climate. The manures recommended, and the method of applying them, are similar to those described in article GARDEN BEAN; but as the manurial effects should take place as soon after they are applied as possible, it is better that these should be in a liquid state.

*Forcing.*—This esteemed legumen can be had in great perfection throughout the whole year. To afford a supply during winter, seeds of the most approved sorts, such as early six-weeks, Fulmer's early dwarf, Wilmot's forcing, &c. should be sown about the latter end of September or 1st of October, presuming two distinct crops are already progressing in pits capable of being so heated as to not only repel frost, of which this plant is impatient, but also to afford a minimum temperature of 60°. Sow in small 60-sized pots, one bean in each, in rather light, dry, rich soil. Place them in a glazed pit or frame, in a temperature maintained at not less than 60° or 65°, keeping the pots near to the glass. When they have attained the height of 3 or 4 inches, transplant them into 7-inch pots, placing 3 plants in each, having their roots and ball entire, so that they may sustain no check in their growth. At potting, place in the bottom of each pot, over the drainage, 2 inches of very rich but much decayed manure, and use a rich, light, rather turfy fresh soil for the roots to work in. Some, at potting, set the plants deep in the pots, with a view to add fresh soil around the stems afterwards. This is an absurd practice, as the roots of leguminous plants very rarely are emitted from the stem, and the consequence of this deep potting is to limit greatly the space for the roots to seek food in. As the natural temperature of the season declines, raise that in the pit or frame in which they are placed to 65° as a night temperature, and 75° as that of the day, allowing a rise of a few degrees in bright sunny days. In a pit heated by hot water, they will succeed better than elsewhere; and, in default of such accommodation, set them on suspended shelves over the footpaths of the pine-stoves, but as close to the glass as will admit of their attaining the height of 10 or 12 inches. To lessen the labour of watering, place pans or feeders under the pots, and syringe the plants frequently, to keep down the thrip and red-spider, which are their greatest enemies. As the plants advance in growth, support them with small twigs to prevent their being broken by the force of syringing. Place a little liquid manure in the feeding-pans, to give additional food to their roots as soon as they appear to wish to escape

through the holes in the bottom of the pots. For this purpose we use cow or horse urine, or liquid guano, as affording ammoniacal fumes, at least to such an extent as experience has led us to believe is very effective in keeping down both thrip and red-spider. Ventilate upon all fitting occasions, but avoid allowing cold draughts of air to blow on the plants at all times; and, as a security against this, cause the air admitted to pass through a thin canvass screen, which will break its force, and so sift it into minute divisions that little injury need be apprehended. To maintain a regular succession, sow every ten days throughout the winter. So valuable a vegetable deserves a heated pit for its special accommodation; and by having one heated by hot water of 60 feet in length, divided into three compartments, a good supply may be kept up. For spring use, should they not be required throughout the winter, the 1st of January may be considered a very proper season to sow. Should the pit into which they are set have been occupied with melons, cucumbers, tomatos, or such plants as are subject to thrip and red-spider, as a wise precaution, previous to arranging it for French beans, let it be cleared of all its internal contents, well brushed out with a birch broom, the lights put in, and every crevice and hole carefully stopped up, and burn within it half a pound of brimstone, keeping the fumes in from night till morning: remove the lights, and whitewash the walls with hot lime-water, and wash the whole of the wood-work with hot water, if painting be at the time considered unnecessary. This is a very necessary precaution to be taken against the insidious attacks of two of the greatest, although minutest, enemies the cultivator has to contend with.

French beans cannot be grown during winter in a temperature of less than 60°—if ranging from that to 65° and 70°, and 80° during the day, so much the better; and where a bottom temperature a few degrees higher can be afforded, so much the more certain will be the success of the crop. They also, in common with all thin-leaved plants of tropical origin, require the fullest amount of light our gloomy atmosphere is capable of affording them; and hence they succeed best in

low pits, or on shelves suspended near the glass. Moisture, accompanied with heat, is also essential; without this, they would become the prey of thrip and red-spider. In addition to the sorts we have already named, may be mentioned the recently-described variety, Newington wonder, which from its dwarf habit is well calculated for suspended shelves in hothouses, occupying less room than any of the other popular sorts. It does not appear to stand the process of transplanting, and should therefore be sown at once in the pots it is to be grown in, putting four or five beans in pots of 6 or 7 inches across. It does not require topping, as most others do; nor, indeed, does it bear such a process with impunity. Give little water to the roots of any transplanted French beans, until the roots have pretty well filled the pots,—after which they will require it more or less, according to the size of the pots they are grown in; those in small pots, of course, requiring the most. Water sparingly, if at all, after planting the seeds: it is time enough when they have begun to sprout, and when their roots are far enough advanced to be able to avail themselves of it. Topping the plants is practised by many, and no doubt those of rambling habits require it, to cause them to become more bushy, and hence to produce a greater number of pods. The time and manner of doing this is as soon as the cotyledons, or two first embryo leaves, are fully developed; and then the central shoot, which will also be making its appearance, should be carefully pinched or cut out. This process, however, somewhat retards the growth of the plant at first; but if time is not an object, the advantage will be apparent in a more abundant crop.

*Approved sorts, and their qualities.*—The varieties of kidney beans cultivated in Britain are in reality not nearly so numerous as the long list of names in some seed-lists would lead us to believe. In France, Spain, and other countries, where they are much more used as an article of food, and where the climate is favourable for their production in the open air, with as little trouble, and for as long a continuance, as our common broad bean, the varieties are endless, and, as is the case with peas with ourselves, continually increasing in number.

1. *The early Dutch dwarf.*—One of the oldest, if not the very oldest, cultivated variety. Pods long and narrow; beans small, compressed, and, when ripe, of a white colour. A good early variety,

and often employed for forcing, being of a dwarf habit. It is known as white long pod Dutch, early dwarf white, large white dwarf Dutch, dwarf Dutch, dwarf white Dutch. It is the *nain hâtif de Hollande*, *nain de Hollande très hâtif* of the French.

2. *Early white.*—Both pods and beans of moderate size; plant very dwarf, from 9 to 11 inches; very early, and on this account, and its small size, well adapted for forcing. The pods are eaten both while green and when the seeds are ripe. It is known as early Laon and dwarf white. It is the *nain hâtif de Laon*, or *flageolet*, of the French. The seeds when ripe are white.

3. *Dwarf Canterbury.*—This is a very old and esteemed variety, hardy and useful. Pods medium length, narrow; beans small, oblong, white when ripe, branching much near the ground; early and productive. It is so near akin to the dwarf Battersea, early white, and earliest white Battersea, as not to be worth cultivating as a separate sort; and its relations with what is called dwarf sabre, sabre nain, dwarf French white, are nearly, if not altogether, as close. It is probable two crops of dwarf Canterbury would afford all these supposed varieties. We think that dwarf Battersea ought to be the established name, in preference to dwarf Canterbury, as we find it has been cultivated above a century under the former name.

4. *Fulmer's early dwarf.*—An excellent forcing variety; pods long, narrow; beans small, dun when ripe. Known also as Fulmer's new dwarf, Fulmer's early, Fulmer's dwarf red, early dun, dwarf dun coloured, dwarf forcing dun coloured, earliest forcing, early frame. Mr R. Thompson, in his excellent papers in the "Gardeners' Chronicle," on the varieties of vegetables, remarks—"Close allied to the preceding is Fulmer's speckled dwarf, *alias* dwarf red speckled, dwarf light-red speckled, early dwarf-forcing speckled, large forcing dark-red speckled, *Suisse rouge*; and with beans a shade darker, we have also, very similar to the above, the early dwarf purple speckled, *alias* early purple, dwarf purple speckled, dwarf speckled. Allowing for another shade darker, and we may include with those the dwarf black speckled, *alias* dwarf black mottled."

5. *Wilmot's forcing cream speckled.*—An excellent forcing variety. Pods long, of uniform breadth; remarkable for crispness while green, and an excellent bearer. Not a great way, however, removed from the last, but sufficiently distant. Beans, when ripe, oblong, pale dun, speckled with dark chestnut.

6. *Black Belgian.*—Pods long, of uniform breadth; crisp, very productive, and a good forcer. Dwarfier and earlier than the dwarf negro, which it somewhat resembles. This is much cultivated in Belgium, and there known as *haricot noir de Belgique*.

Mr Thompson thus notices the bean, in the "Journal of the Horticultural Society of London," vol. v. :—"Although the variety has been previously noticed" (in the Journal), "yet the present mention of it will doubtless be excused,

for it may be usefully stated that it is the best both for early and late sowing. It is dwarf, and may be sown in pots before the open ground has acquired sufficient warmth; and if planted out when this is the case, it soon comes into bearing. Again, late in summer, when later sorts would not even blossom, if then sown, the sort in question would produce a good crop, that will keep in gathering condition till cut off by frost. This and the *Newington wonder* are considered the best varieties of dwarf kidney beans."

7. *Dwarf speckled China*.—An early dwarf variety, and abundant bearer, well suited for forcing. Pods smallish, uniform in size. Beans, when ripe, of a clear sulphur colour. Known also as early dwarf pink-spotted: why called pink-spotted, it is difficult to comprehend. Robin's egg, dwarf robin's egg (from the small size of the bean), dwarf China, early China. It is the haricot de la Chine of the French.

8. *Dwarf negro*.—A popular variety; pods of moderate size, uniform in size and breadth; exceedingly productive; dwarf and hardy; well suited for forcing. Beans, when ripe, quite black. Known as early negro, early black. It is the *nain noir* or negro of the French.

The dwarf negro is the favourite in the London market, on account of their being all green, and not marked or blotched, like some others. They are also all one breadth, very narrow and handsome; and they are very dwarf, and first-rate bearers.

9. *Long-podded negro*.—A new variety of the last, vastly superior to it; the pods being often nearly seven inches in length, and of very uniform breadth: rather a strong grower, and admirably suited for a general crop.

"These are often sown amongst lettuce, 6 feet apart, about the 1st of April; but by far the best plan is to sow in beds thickly, and transplant by means of the dibber. No plant lifts better, and the moving makes them show flower much sooner. The usual practice is to take the heads off the plants, leaving them a foot high, and to keep topping all the summer, which induces them to bear heavy crops. But the way to get them to bear earliest, is to save the roots in autumn, pack them away like dahlia roots, and to transplant them again in March, 6 inches root from root, in rows 5 feet apart. It should be borne in mind, that if beans are left to ripen, the roots will not be near so strong as they otherwise would be."—CUTHILL in *Market-Gardening around London*, p. 24.

10. *Long-podded China*, an improvement on No. 7, having pods from 6 to 7 inches long; exceedingly crisp; of uniform size and breadth; very productive; and, like the last, good for a general crop.

11. *Newington wonder*.—Another recently-produced variety, of great excellence as a forcer, being of dwarf habit; large pods of good shape; does not bear transplanting well.

The following description of this excellent bean is extracted from the "*Journal of the Horticultural Society*" (vol. v.):—"Very dwarf; about a foot high; early and productive. The

Pods are moderately long, not very broad; but having thick fleshy sides, within which the seeds form but slowly; and the pods remain long crisp; their colour is dark green. It may be planted in rows 18 inches apart."

12. *Early six-weeks*.—A small early bean well suited for forcing. The Mohawk and Victoria speckled are early sorts, and well worth cultivation.

13. *Sabre*.—One of the largest, in point of size of pod, which is used for ordinary purposes, until it attains its full size continuing crisp and tender. In this state it is often cut into alices, and preserved by salting, in which state it will keep for a long time. The beans, in a dried state, are esteemed in haricots. It attains a height of from 2 to 3 feet, and therefore is benefited by being supported by short stakes like dwarf pease. It is a profitable sort where there is plenty of room.

14. *Large running white*.—Another tallish-growing sort, cultivated extensively on the Continent for its seeds, which form the large white bean or haricot, so very generally used in dishes of that name. It is seldom cultivated in Britain, nor could it be profitably cultivated for that purpose. It is known in our seed-lists as tender-podded bean, runner, long white, large white sugar, white long pod. It is the *sabre à très grande cossée* de Soissons— from Soissons, where it is cultivated to great perfection.

15. *Bush haricot*.—About 15 inches in height, branching close to the ground, and branching out in succession; not only continues to produce a long continuation of crop, but, by shading the ground, keeps it moist in dry seasons. Pods 5 inches long, and produced in great abundance; being crisp, transparent, and excellent, comes early into use, and continues long in bearing. The dry seed is speckled red and white. It is the haricot solitaire of the French and Belgians: in both countries it is grown extensively.

There are many other names met with in seed-lists, such as dwarf Canadian, liver-coloured, early yellow, large pearl, small do, magpie, grey, marbled Prague, round dwarf, &c., which, if not identical with some of the above, are inferior to them in quality.

Amongst the newer sorts of kidney beans the following deserve notice—not, however, that they will ever supersede the dwarfer kinds already noticed for general crops, yet some of them may be found acceptable, under peculiar circumstances, in private gardens.

*Haricot d'Alger* is stated, in the "*Bon Jardinier*" for 1850, as being excellent and long cultivated in Lorraine. Pod of a palish-green colour, destitute of any tough lining, and exceedingly tender and excellent when cooked. The plants rise to the height of 2 or 3 feet, and therefore require support, but may be dwarfed by early topping.

*Turkische bhone*.—It is thus described in the "*Bon Jardinier*":—"This variety is perhaps the best of all; it bears tolerably well; its pods are of an extraordinary length and breadth" (from 12 to 14 inches in length and upwards of an inch in breadth); "in a young state they make

excellent haricot verts; when nearly full-sized, they are still tender and fleshy, and may be used in this state, either fresh, being broken in small pieces; or, in winter, after being cut into narrow strips and preserved with salt." These were tried in the gardens of the London Horticultural Society, and, notwithstanding the cold state of the ground and unfavourable season, some of the pods attained the length of 10 inches, and nearly 1 inch in breadth. The expectation was that they would attain their full size in a good season. Mr R. Thompson thinks them, however, the same as the haricot sabre d'Allemagne of Noisette's "Manual du Jardinier," and the sabre of the "Bon Jardinier." They attain a considerable height, requiring stakes. The pods are large and crooked, and tender while the seeds are under half their growth; it is not so abundant a bearer, nor does it continue so long in use, as the haricot aolitaire. It is, however, on account of the size of its pods, worth cultivation.

There are a number of French varieties now in the seed-shops, many of which, although very excellent in a better climate, would be unprofitable in such a climate as ours.

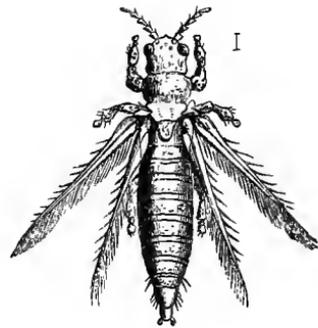

The following selection from the above may be considered sufficient for an ordinary garden: No. 1, 3, 4, 5, 9, 11, and 13 for particular purposes.

Shilling's new French bean, a very prolific sort; pods large, and remaining long tender. Wilmot's true forcing, excellent for that purpose. Black Belgian, negro, cream-coloured, and early Dutch. The last five are the sorts we usually grow.

*Insects and diseases.*—The most destructive of these, always in the forcing-houses, and often during dry warm weather in the open air, are the thrip and red-spider, both pretty numerous in species, and, as individuals, as incalculable as the sand on the sea-shore, while their minuteness renders them almost invisible to the naked eye. Indeed, they may be set down as among the worst enemies the cultivator has to contend with. Fortunately, however, our hot-houses are infested with only two species of the former, both of which are considered of exotic origin. In the open air many of the species attack plants. The same means employed to destroy one species are fatal to the others also. The genus is thus described by the writer of the excellent articles on entomology in "The Gardeners' Chronicle," 1841 (p. 228):—"They vary very considerably in colour, some species being black, others have the wings branded with white, but the general tint of the larvæ and pupæ is yellow-ochre. Their bodies are much depressed, and much broader than any other part in the female; the mouth is placed under, and at the hinder part of the face, and forms a short conical rostrum, lying when at rest close to the base of the fore-legs. The eyes are rather large and coarsely granulated, and there are generally three ocelli or simple eyes on the crown of the head; the horns are eight or nine jointed, but the three last joints often appear to be united, when they look as if only six or seven jointed, especially in the larvæ state; they are either wingless, or they have four wings,

which are narrow, and lie down the centre of the back, the edges being ciliated with long hairs; the legs are short, the feet being formed of two joints with a vesicle or little bladder at the apex, but not any claws. The larvæ resemble the perfect insect in form, but are often of a totally different colour; their bodies are soft, and they have no ocelli. The pupa is also similar, but the wings are sheathed, and the horns are generally thrown over the head. Some of the species are very active when they have arrived at their perfect state, running fast, skipping and flying well; and they are able to walk about in their previous stages. The two sorts most injurious to the gardener are a little ochreous species, which does not appear to be described, and the *Thrips adonidum*, fig. 21. The first I shall name *T. ochraceus*;

Fig. 21.

THE THRIP.

it is narrow and linear; of a bright and deep ochreous colour; the eyes are black; the horns appear to be only six-jointed, and brownish at the tips; it has three ocelli on the crown; the body is hairy; the tip pointed and bristly; the wings are shorter than the body in the male, lying parallel on the back when at rest; narrow, especially the under ones, and fringed; the hairs longest beneath and at the points; tips of feet dusky. There is so great variety in the form and structure of this family that it has been divided into several genera, to one of which belongs the other species called by Mr Halliday *Heliothrips adonidum*. The larvæ and pupæ are yellowish white, and the perfect insect is of a dull deep black, with the point and sometimes the whole abdomen of a rust colour; the wings are dirty white, the horns and legs yellowish, the extremity of the former black; it is a little larger than *T. ochraceus*, and is very troublesome in hothouses, attacking tropical plants by piercing the under side of the leaves; and one often sees at the top of the tail a globule of blackish fluid, which it soon deposits, and by innumerable spots of this glutinous matter the pores of the leaves are stopped up, and large portions of the surface become blotched. I have found specimens in October, but during March the full-grown larvæ and pupæ, which are as large as the perfect insect, are found in groups feeding on the under side

of the leaves; and at this time the recently-hatched and perfect insect either lies close under the ribs, or roves about in search of a mate. As this species is imported from some tropical region, it can endure great vapour-heat, and is consequently most difficult to extirpate."

The same means for their destruction have been employed that have been used against its equally tenacious neighbour the red spider, for they are generally found together. A dry high atmosphere is favourable for the production of both: their destruction may be completely effected by the means stated above—viz., the powerful fumes of sulphur; but this can only be employed to destroy such as lurk about the wood-work or building; or, in the case of deciduous plants like the vine and peach, while these are in a dormant state. With plants which retain their leaves, and with plants in a growing state, this application cannot be employed; for far less of such fumes that would destroy the insects would utterly kill the plants which the remedy was intended to cure.—(Vide *Red Spider* for other remedies.)

The Red Spider, fig. 22, is really no spider at all, but one of the mites, a very numerous and destructive race. It is doubtful if what is generally called the red spider is really only one species of insect, from the different appearances it assumes, the different positions it occupies, and the variety of plants which it attacks. It is in general considered to be the *Acarus telarius* of Linnæus, and has been a scourge to cultivators since his days. Like the thrip, it is of exotic

Fig. 22.

THE RED SPIDER.

origin, present always in hothouses where a sufficient temperature is maintained, and in greatest activity when that temperature is accompanied with an unusual degree of dryness—a fact pretty well established, as it never makes its appearance in a low temperature accompanied with moisture. In warm and dry summers it does great injury to vegetation, few plants escaping its attacks: to French or kidney beans it is most destructive, both in houses and in the open air. When very abundant, it has the faculty of spinning a web, and forming for itself a pretty secure retreat: from this circumstance it has obtained the name of spider, as well as the specific one *telarius*. Its mode of operation is to pierce the under side of the leaves, and to imbibe the juice, causing little yellow spots on the upper surface of the leaf at first, which soon spread, and give to the whole leaf an autumnal tint: as their attacks increase, discolouration goes on, until the tree or plant becomes so exhausted that it sheds its leaves, and smaller plants often actually die in consequence. The kidney bean is a familiar example of this.

"The red spider, if magnified, looks like a crab of an oval form, with the legs so arranged

that two pair are directed forward, and two pair incline backward: it has a few long scattered hairs, and is of a somewhat transparent yellowish white, more or less inclining to orange, with a blood-coloured dot or spot on either side of the thorax; the larger specimens, which appear to be females, have a bright chestnut-coloured body, the fore part of the thorax being ochreous, while the smaller ones have a lead-coloured patch on each side: unlike spiders, the thorax and body are so united that they form one mass; the head is narrowed and rounded, and from under the nose projects a short rostrum, composed, I believe, of two lateral valves, enclosing two fine bristles, which can be thrust out at the pleasure of the animal. Many of the acari have two feelers, like an additional pair of short legs, projecting from the head, but in this species they are very short and only two-jointed, and I cannot discover any eyes: the legs, which are nearly of equal size, are clothed with movable bristles, and seem to be composed of five joints, besides a minute vessel at the tip, from which proceeds a pair of bristly claws. The female is oviparous, and exceedingly prolific; the eggs hatch in eight days, and it is very remarkable that, when first excluded, the young red spider has only six legs, the third pair being wanting; but this pair is attained when the insect changes its skin. A variety of sizes is apparent amongst them, independently of differences in the sexes, the females being the largest, with the oviduct slightly projecting; and quantities of their cast-off skins are scattered about the under side of the leaves which they inhabit."

—RURICOLA in *Gardeners' Chronicle* 1841, p. 164.

Syringing with considerable force has been of advantage in disturbing the insect, and no doubt driving many of them off the leaves: water at 150° has been employed with beneficial effect. The means we have stated above are completely efficacious in ridding empty structures of them, but cannot be applied to living plants. A modification of this is to paint the flues or hot-water pipes slightly with a paint of sulphur and water, but the heated body must not exceed the temperature of 212°. Applying sulphur, either by burning it at a low temperature, syringing the trees with it mixed in water, or applying it in a dry powdered state, by means of the new invented sulphurators, and painting the branches with it, as well as, in the case of trees on the walls, the walls themselves—adding to it in any of these cases, except upon heated bodies, a small portion of soap, to make it adhere longer to the branches or leaves—are all efficacious. In any of these ways the insect may be subdued, if not completely destroyed, if taken in time and applied with vigour; but, like medicine, if put off too long, or taken in insufficient doses, and even in full doses not followed up according to prescription, all will be labour in vain. To crops in the open air, such as kidney beans, it may be readily applied by the sulphurators, or mixed with water poured over the leaves from the rose of a watering-pot. Ruricola, in "*Gardeners' Chronicle*," 1841 (p. 166), says, "A quarter of a pound of flour of sulphur—put into a watering-pot of water, and, when

well stirred, poured through a rose along the flues when they are warm, or brushed over the steam pipes, but not after the foliage has expanded—produces the necessary effect, and in course of a week the plants should be well syringed." The same weight may be put to the same quantity of water when applied to kidney beans or other crops in the open air. The warmer the weather when the sulphur is applied, for obvious reasons, the better.

#### § 4.—THE SCARLET RUNNER.

*Natural history.*—Scarlet runner (*Phaseolus multiflorus*, Wild.) belongs to the same natural order, and class and order in the Linnæan arrangement as the last. Although the scarlet runner is not so early as the kidney bean, it nevertheless produces a much larger crop of pods as excellent, and to some tasting better than the other. In Britain the green pods only are used; on the Continent, the ripened seeds are as much an object of culture. "In Holland the runners are grown in every cottage-garden for both purposes; and in France and Switzerland it is grown chiefly for the ripened seeds: in the latter countries it is grown on very poor soil."—*Encyclopædia of Plants*, p. 616. The seeds are preserved in the pods attached to the straw, and are in winter thrashed out and boiled, and eaten with cream or butter, stewed in haricots or put into soups. The scarlet runner, although in general cultivated as, and considered to be, an annual like the kidney bean, is truly perennial. It is stated to be a native of South America, and was introduced into Britain in or before 1633. The French, now enthusiastically partial to this legume, at one time held it in utter detestation. Phillips relates an anecdote of a lady friend of his, who took some of the "seed of the scarlet runner to Jamaica, and by planting them in her garden they were brought to tolerable perfection; but her gardener, who was an old Frenchman, would not by any persuasion allow them to be eaten, on account of the scarlet or blood colour of the blossom." They occupy a place in most cottage-gardens in England, and are made both ornamental and useful. They cover arbours, are trained over pales and up the walls of cottages, which they enliven by the brightness of their blossom, while every day produces a supply of wholesome and nutritious food to the owner.

*Uses.*—The same as those of the kidney bean.

The mode of *propagation* is by sowing the seeds, or by planting the small tuberous roots saved from the last crop. These should be dug up in autumn, before the frost has killed the haulm, and be kept in boxes of sand in a cellar till the end of April, when they may be planted.

*Sowing and planting.*—Being rather more tender than the dwarf sorts of kid-

ney bean, they do not admit of being planted earlier, nor should the tubers be planted sooner, as both may become rotten in the cold damp soil before vegetation can take place. In Scotland, one sowing or planting will be sufficient, as the plants will continue to bear as long as the season lasts. In England, where vegetation is more rapid, and the season longer, later sowing or planting will be necessary, making the difference in the times of sowing about ten or fifteen days. They should be sown in lines not nearer than 12 feet from each other, that being the height to which they will grow if in good soil, and supported with stakes so high. 9 feet may, however, be taken as an average height; and as that is more than can be conveniently reached from the ground, a greater height would be next to useless. The seed being larger than those of the kidney bean, the drills, whether for planting the seed or the tubers, should be not less than 3 inches deep, and the seed or roots placed 9 inches distant in the line.

*Subsequent culture.*—What has been said regarding the pea is quite applicable to this crop also: when the haulm has reached the height of 8 or 9 feet, it should be topped, for reasons given (*vide* KIDNEY BEAN, PEA, &c.) If the production of pods be greater than the consumption, the oldest should be picked off before the seed is much more than formed in them, as, if left on, the plants would be unnecessarily weakened, and the continuance of the crop much diminished. Where stakes are difficult to procure, the runners may be topped when 2 or 2½ feet high. This dwarfing, although it lessens the produce, nevertheless admits of good crops being obtained.

In staking runners, long slender rods are preferable to the branching sticks used for pease. These should be stuck along both sides of the row, as soon as the plants are 6 inches in height, and placed in a diagonal direction, reversed on each side, so that, when the row is finished, the supports will have the appearance of diamonded trellis-work. The intention of setting the stakes in this manner is to afford a more ready means to the stems of the plants to ascend by and twine round. These rods should meet at top, for, unlike the pea, which branches

out as it ascends, and therefore requires to be kept more open at top, the runners branch most near the bottom, and are thinly furnished with side branches towards the top. As noticed for pease, strong wide-meshed netting, attached to poles driven in along the rows, may be very advantageously used where rods are scarce; and poles, furnished with cross pieces of lath, about a foot in length, nailed to them, will serve well for attaching tarred cord or common twine to their ends, and thus enclose the plants between three, four, or five lines of cord, according to their height. A very good way of training is to plant two rows 4 feet apart, to procure rods of sufficient length to admit of their thicker ends being thrust into the line of each row. The smaller ends may be brought together at the top, thus forming an arch or curvilinear trellis. These rods, if sufficiently strong, need not be nearer each other than 3 or 4 feet; and lines of cord should be stretched from one to the other, taking a turn round each in passing, and extending the length of the rows. Four or five lines of cord thus fastened will form a very excellent trellis for the runners to grow over, and form at the same time a nice shady arbour. Three larch poles, set in a triangular form, and fixed together at the summit, form a good pyramidal conductor for such plants. The London market-gardeners' practice is to top the plants when they begin to form pods; and when the object is to gather the crop in a green state, immense quantities are thus produced. Where, however, seed is to be ripened, in this country at least, stakes are found to be indispensable. Cottagers may attach cords to the wall under the eaves of their house, fastening the lower end to stumps of stick driven into the ground. If a prepared border is made along the bottom of the wall, and the beans set in it, they will entwine themselves around the cords, and thus improve the appearance of the cottage, and afford an excellent supply of a nutritious vegetable food.

*Soil and manure.*—A soil richer, and even deeper, than that suited to the pea is in this case required. In newly-broke-up soils, all the leguminosæ prosper well; and in older ones, if rich in humus, they produce wonderful crops. Light, poor, or

gravelly land, although it hastens the maturity of the crop, is incapable of yielding such returns as those we have stated.

*Forcing.*—The scarlet runner, on account of its rambling growth, is unsuited for the forcing-house, and hence is never obtained earlier than the period of its natural growth.

*Taking the crop, and subsequent preservation.*—The young pods are gathered when from  $2\frac{1}{2}$  to  $3\frac{1}{2}$  inches in length, and before the seed begins to form within them. When rapidly grown, they may be used of a larger size, and in that case they are cut into long narrow slices when about to be dressed. When the seeds have fully formed in them, they are unfit for use in their green state. When grown for their seed, whether for future sowing or for haricots, they are pulled up when fully ripe, dried in the sun and stacked by, and afterwards separated from the pods for use, either by being thrashed out or by hand-picking, and the seed bagged or otherwise stored by till wanted.

*Approved sorts, and their qualities.* 1. *Scarlet runner.*—Attains the height of from 9 to 12 feet; flowers beautiful red, and abundant; pods rough on the outside; nevertheless they are, while young, as crisp and as well flavoured as any of the dwarf sorts; beans, when dry, dark red and spotted. Known also as the tall scarlet runner, a mere seed-list name. It is the Haricot d'Espagne, or écarlate, of the French.

2. *White Dutch runner.*—Pods rather longer and smoother than in the last; flowers and beans white; does not continue so long in a bearing state as the last; is known as the case-knife runner; scarcely attaining so great a height as the last.

3. *Painted lady.*—Resembling the last two in habit; the flowers, however, are variegated, being of a bright scarlet colour, intermingled with pure white, and hence very ornamental; not so productive as the last two, nor quite so delicate to eat. We believe this to be the same as the York and Lancaster runner of some seed-catalogues. It is the Haricot d'Espagne, à fleur bicolore, or panache, of the French.

These are the principal sorts in cultivation in Britain. The Americans possess many varieties of haricots, such as the Lima pole bean, but, like the Sieva and other sorts, they are by far too tender for our climate; and the same may be said of several European sorts, which, upon trial, are either too tender, or inferior to those named above. Of these we may name the Prague runner, or red pea, which, although related more to the true kidney bean than to the section in which the three above runners stand, has some merits also, the pods being tender, while the seed is round, and, when ripe, rather thick-

skinned, mealy, and in flavour resembling the sweet chestnut. The *Haricot d'Alger*, Prague bicolor, Prague jaspé, are varieties of the Prague runner, the beans of all of which become soon unfit for use.

*Insects and diseases.*—These are the same as those attacking the order leguminosæ generally, and the kidney bean in particular (*which see*). The seed of all the runners cannot be depended upon to vegetate above a year. Besides the insects noticed in article KIDNEY BEAN, all the leguminosæ are liable to the attacks of slugs and snails, from the time they appear above ground until they attain the height of a foot or so, after which they seldom trouble them. Their destruction is simple: dusting the plants morning and evening with caustic lime in powder, as recommended for pease, will soon rid the plants of these pests.

*General remarks.*—There have been few substitutes found for any of the leguminous plants which are cultivated as articles of food. The white lupin, *Lupinus albus*, has from the earliest ages been extensively grown in Spain, Portugal,

and Italy for the ripe seed, which is used in the same manner that haricots are by the French.

Several species of lentil are cultivated on the Continent also for soups and haricots: these are chiefly *Ervum lens*, the common lentil; *E. Ervilia*, the winter lentil; *Lathyrus sativus*, the Spanish lentil; *Cicer arietinum*, the chick pea, &c. Both lentils and lupinus are cultivated in Italy now, as they were in the days of Pliny, as green manure, being ploughed or dug in when they had attained their greatest size, but before they had formed their seed, in which case it was supposed they would rob the ground of more than they restored to it. This remains a question for modern chemists to solve. Pliny states that beans also were cultivated in the vicinity of Macedonia and Thessaly for the avowed purpose of being dug into the ground, and that this was done just as they began to bloom.

One lb. of liver-coloured kidney beans (which sort is of medium size and weight) contains 792 beans. One lb. of scarlet runners contains 428 beans.

## CHAPTER III.

### BRASSICACEOUS PLANTS, OR THE CABBAGE TRIBE.

THE natural order to which the Brassicaceous plants belongs, contains plants of the greatest importance to man. The whole order is pre-eminently European: 166 species are found in the north and middle of Europe, and 178 on the shores of the Mediterranean. Dividing them into the two hemispherical divisions of the globe, it appears that while only about 100 species are natives of the southern, there are about 800 natives of the northern. "The useful qualities of the turnip, radish, the rape, and the cabbage, and all its multiform varieties, are all well known. The greater part of the order consists of plants possessing high anti-scorbutic powers. These appear to depend upon a certain acrid, volatile, oily principle, the chemical nature of which is imperfectly known. It is to be remarked that plants of this order are always eatable when their texture is succulent and watery, as in the roots of the radish and the turnip, and the leaves of the cabbage tribe. Cruciferæ are said to possess a greater share of azote than any other tribe of plants, as is apparent in their fetid smell when fermented."—*Hortus Britannicus*.

#### § 1.—THE CABBAGE.

*Natural history.*—*Brassica oleracea* is the type of a numerous family, consisting of the white and red cabbage, cauliflower, broccoli, savoy, Brussels sprouts, and the borecoles, all of which are believed to have sprung from the wild cabbage (*Brassica oleracea*), specimens of which are to be found on the sea-shore at Dover, and at various other places in our own country, as well as in some other parts of Europe, but always in chalky or calcareous soil. Botanically, it ranks in the natural order Cruciferæ,

sub-order Orthoploceæ (from *orthos*, upright; *ploke*, fold—cotyledons), and tribe Brassicæ (*Orthoploceæ siliquosæ*); and stands in class Tetradynamia and order Siliquosæ in the Linnæan arrangement.

The name is derived from Bresic, the Celtic name of the cabbage. Brassica was the name by which it was recognised by the ancient Romans, proceeding from *præseco*, because it was cut off from the stalk. The Latins gave it the name of *caulis*, from which our modern names cole, colewort, are derived. The term cabbage is in general understood to mean those varieties which form a firm head, by reason of the leaves turning close over each other, in contradistinction to those open kinds, like the borecoles, &c., which are called kales. Three varieties of cole are mentioned by the eldest Greek historians—the crisped, or ruffled, which they called Selinas or Selinoides, from its resemblance to parsley; the other, Lea; and the third, Corambe. Chrysippus and Dieuches, two learned Greek physicians, each wrote a book on the properties of this plant, and Cato and Pythagoras wrote in its praise. Apicius loathed them, and Drusus Cæsar held them in no esteem, while his father, the Emperor Tiberius, thought highly of them. The discovery of the art of distillation is attributed to the simple circumstance of an ancient physician having been called suddenly away from a mess of cabbage he was eating; he placed another plate over that in which his cabbage was, to keep them warm, and finding, on his return, the interior of the uppermost plate covered with moisture, he reasoned on the cause, and ultimately discovered the art of distillation.

The introduction of the cultivated cabbage into Britain was no doubt the work of the Romans; and its dissemination afterwards may be attributed to the earliest ecclesiastic communities, who ever had an eye to the good things of this life. In all probability it would reach Scotland and Ireland by the same means, although it has been asserted that it was scarcely known in the former country till the time of Cromwell, whose soldiers are said to have brought it with them from England. Gerard is the oldest English author who has written fully on this useful vegetable; he mentions the white-cabbage cole, the red-cabbage cole, the curled gar-

den cole: "the Savoie cole is," he says, "numbered amongst the headed coleworts or cabbages." He notices the curled Savoy, but says, "the swollen colewort of all others is the strongest," and which he received from Master Nicholas Lete, who brought the seed out of France. The same author says, "Rape cole is another variety; they were called in Latin *caulo-rapum* and *rapo-caulis*—participating of two plants, the coleworts and turnips, from whence they derive their name. They grow in Italy and Spain, and some places in Germanic, from whence I have received seeds for my garden. 'They must,' he says, 'be carefully set and sown, as musk melons and cucumbers.' This variety has now become one of our hardiest field plants."—PHILLIPS.

There is scarcely an instance in the whole vegetable kingdom of a plant that has produced so great a number of varieties, differing so much in appearance and qualities, as the *Brassica oleracea*: few would suppose that the wild cabbage found on our sea-shore is the parent of such a progeny. In its natural state, with its green wavy leaves, without the appearance of a head, and, to superficial observers, scarcely distinguished from the wild mustard or charlock, it is as dissimilar to one of its own offspring, the drumhead cabbage, as it is to a Tarragonian grown cauliflower, which is said often to attain the weight of 40 lb.

*Use.*—In a variety of forms this esculent is in almost universal use throughout the whole civilised world. The Greeks and Romans used it in a raw state, to counteract the intoxicating effects of wine. One modern physician, at least, has recommended it for a like purpose. The Romans threw trefoil and nitre into the pot along with the cabbage, believing that such would cause them to boil green—a department in cookery in which many good housewives plume themselves not a little at this day. All vegetables, if fresh gathered, may be boiled without the least change in colour, if put into *boiling water* with a handful of *salt*, and allowed to boil in *plenty of water*, leaving the vessel uncovered. The uses to which it was applied by the ancients are given by Phillips, in his "History of Cultivated Vegetables," vol. ii. p. 99, summing up the whole with the observation that they believed it "light of digestion, and that it clarified the senses when moderately eaten."

The large drumhead cabbage is used extensively in Germany, and throughout the north of Europe, for making saur-kraut. The heads are cut into small shreds with a knife or plane made for the purpose, are packed in barrels or tubs along with vinegar, to which salt and cloves are sometimes added, and in this state they are preserved in excellent condition till late in spring: when used, it is stewed over a slow fire, and served up with most kinds of meat. In England they are pickled, and used for the same purposes as the red cabbage, which latter is grown principally in Britain for pickling. On the Continent it is much esteemed when slowly stewed in an earthen pan, along with a few slices of onion, and a larger propor-

tion of apples, in which state it appears at most tables during winter, and is both excellent and wholesome. In all cases the cabbage is most wholesome when eaten young; and hence the English, and the Scotch now following their example, prefer them in the form of collards, cabbage-plants, or cabbage-sprouts, and like to see them brought to the table quite green and tender. In country places in England, and in most of our Scotch green-markets, they are only to be found when of a large size, thoroughly hearted, blanched white within; in which case they are, particularly when long cut, exceedingly unwholesome, often tough, and in general flatulent and indigestible.

*Propagation.*—All the varieties of Brassicæ are raised from seed annually, but they may all be also propagated by cuttings—a method employed to preserve any particular variety from changing its character, which all are exceedingly liable to do when propagated by seed, on account of the natural disposition of the plants to shoot into hybrids. Hence our seed-lists are so crowded with names, and hence also the difficulty we often experience in getting seed which will produce plants identical with their parent.

Almost all the Brassicæ produce sprouts—the cauliflower and broccoli less freely than the others. By means of these, any choice kind can be increased by cuttings, and thus perpetuate the identical variety without the chances of its becoming deteriorated by rearing them from seed. However carefully seed of this family is saved, we are never certain in the results, and what we may have genuine and pure one year may become, by intercourse between neighbouring plants of the same family, next to useless another. The idea of propagating them by extension—that is, by cuttings—did not, however, arise from this alone. It was introduced into England about thirty years ago from the Brazils, where the climate is too hot for the cabbage to perfect its seeds. The manner of proceeding is this:—The sprouts, when from 4 to 5 inches long, are taken from the stem of the plant, and, according to their state of succulency, are exposed to the atmosphere to cauterise the wounded part. In summer, a day and a night is in general sufficient; while in winter two or three days may be requisite. The cut end of the sprout is dipped in caustic lime or dry wood-ashes, to dry up the moisture. They are then

planted like any other cutting—producing, in due time, plants fit for use, and cuttings for further propagating supplies. Amateurs might in this way keep up a succession of stock without the trouble of sowing seed. The great advantage, however, is in keeping the stock uncontaminated.

*Sowing and planting.*—The time of sowing for a principal crop, to come into use the May following, is by long experience fixed by the London market-gardeners to be from the 25th of August to the 1st of September. A fortnight earlier is expedient north of Newcastle, unless in very favourable situations, when the 25th of August may be taken. Much of the danger attending too early sowing is in the plants running to seed in spring without hearting. No doubt there is something in this; but seed of a good variety, and at least a year old, is not liable, under proper management, to do this. It is, however, well to make two sowings in all suspicious cases—the one during the first week, and the second during the last week in the month. Plants from this sowing should be planted out for good by the middle or latter end of October, the plants having been previously removed from the seed-bed as soon as they are fit to handle, and being transplanted into a nursery-bed in what is called the pricking-out manner. The largest of these should be planted first, and the smaller afterwards, which may extend the season of their final planting to the first or second week in November. This is to be considered as affording a general spring or early summer full crop. Towards the end of February or beginning of March, sow, to secure plants fit for planting out in May, June, and July, generally as the ground is cleared of early crops of pease; this will give a supply fit for use during the latter part of summer and autumn. These are the two general sowings. For particular purposes, and in peculiar situations, a sowing will sometimes be required to be made by the beginning of February, to secure an early summer supply, should accidents have come over the crops of the August sowing, and also if it be apprehended that that crop should be insufficient for the supply.

In sowing seed of all the Brassicæ, and at whatever season, there are certain

helpers sent us in the feathered part of the creation, who thin our sowings. In so far they do good, but sometimes they overdo this act of kindness by thinning too much. Now as these are, according to our notions, friends we cannot dispense with, seeing the good services they render us, in a way and by means we could not do for ourselves, we must not, like barbarians, talk of their destruction. We must protect ourselves from their over-officiousness in this matter, by covering our seed-beds with netting closely secured at the edges, but elevated from 9 inches to a foot over the general surface, which is easily done by setting in a few slight branches to support the netting. It is a poor crop that will not repay the trifling trouble and expense of this; and he who thinks the matter of so little consequence to himself as to disregard this precaution, is rightly served to find his seed entirely abstracted. Many other means have been proposed; we know of none so simple and so efficacious. Strewing the surface with lime, wood-ashes, soot, &c., are all very well in their way; suspending half a score of egg-shells from lines run in all directions, stuffed cats, owls, hawks, &c., are the vestiges of the dark ages of horticulture; and even *our first published* potato-danglers, fig. 23, stuck full of feathers, are but sorry preventives.

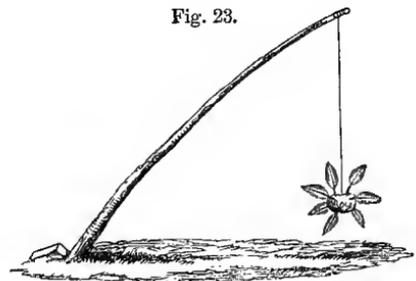

Fig. 23.

SCARECROW.

Seed for what is called cabbage coleworts—that is, young cabbage-plants, to be used while quite young, and, before they indicate hearting, a sort of produce much in use about London, and now becoming general in private gardens—should be sown between the middle of June and the end of July, so as to be fit for final transplanting during August, September,

and October, as ground becomes vacant for this purpose in particular.

Chappel's colewort, not much known beyond the London market, should be sown during July, August, and September, transplanted very close together, and upon all spare pieces of ground, under fruit-trees, &c. They come into use early in winter or spring, and are much esteemed.

Late or drumhead cabbage is sown for general crops either in August, and kept over winter, being planted out in October or November, or early in spring, say February or beginning of March, and planted out in May or June. The former is the Scotch practice, the latter the English.

A great deal depends as to the period of sowing, particularly for main spring crops, upon situation and circumstances. The rule laid down by the London growers in this respect may be taken as the latest period, as every circumstance is in their favour. Not so in cold climates and cold soils; and to meet the requirements of these, the seed should be sown earlier, from a week to a month, according to the unfavourableness of the place and circumstances. To sow too early would make the plants too strong, and certainly endanger their running to seed: to sow too late would be to have plants too weak to stand the winter; and should they even do so, they will be late in coming to perfection. At the July sowing, it oftentimes appears that the ground is dry, in which case it will be of great advantage in securing a strong and rapid germination, to soak the ground with water some hours before putting in the seed; but, to prevent the soil from caking, it will be well to fork it over before sowing. The seed may with advantage, under such circumstances, be also soaked a few hours in tepid water. After sowing, if the weather continue hot and dry, shade the beds with branches or otherwise till the plants appear above ground, when the shading should be gradually removed. As soon as the plants are above ground, dust them over morning and evening with finely-pounded caustic lime, as a precaution against insects.

All the varieties of the Brassicæ, with the exception of the cauliflower and the Couve Tronchuda, or Portugal cabbage, are

exceedingly hardy, and therefore, in all ordinary cases, the most open and exposed situation should be fixed upon for the seed-beds. The exception to this is in cold places, where the early spring sowing will require the shelter of a warm south border, and in many cases the assistance of a slight dung-bed heat. Wherever the seed is sown, it should be freely exposed to the sun and air, and of all things shaded spots should be avoided. The seed should be sown thin. A bed 4 feet wide and 20 feet in length will require 2 ounces for the smallest-growing varieties of early cabbage, such as Aitken's matchless, &c. For those of larger size, such as the vanack, the same quantity of seed will sow a bed 4 feet broad and 36 feet long. One ounce of seed will give from 2000 to 2500 plants. Cover to the depth of  $\frac{1}{4}$  inch from the alleys, if the soil be light and well pulverised; if not, make the surface smooth with the back of a spade, and when the seed is sown, cover with a light compost to the above depth.

All the Brassicaceous tribe are very much improved by transplanting as soon as the young seedling plants are fit to handle, which will be when the young leaves have attained the size of about 2 inches in length. At this time they should be carefully removed from the seed-bed, and, if the weather be dry, the bed should receive a good watering, which will facilitate the operation of lifting without injury to the tender roots of the plants: the nursery-bed should be prepared by previous manuring and digging, and its surface, if dry, well watered previous to planting; and when the young plants are set therein, it should receive a gentle watering, to settle the soil about the roots. If the sun is powerful, a slight shading will be beneficial during the day until the roots have taken hold of the ground. This is more especially necessary for summer transplanted crops. In such nursery-beds, they should remain until well rooted, and, at planting, be set from 3 to 4 inches apart, according to the size of the variety. A second transplanting is often found beneficial to give greater strength to the plants, to encourage the multiplication of roots, &c., but in this second removal they should have a third more space accorded them. By such means plants will attain a good size, and be fit for final

transplanting the moment ground is cleared for them, thus economising both space and time. Those intended to be set in nursery-beds during winter should be planted from 4 to 5 inches apart each way, for too thick planting is injurious in two ways—it draws the plants up slender, and prevents the circulation of air amongst them, by which many damp off during winter. Great care ought to be taken that each sort is kept separate, and that all be correctly labelled to prevent mistakes in spring. The same attention should be paid to Brussels sprouts, savoy, and such kinds of borecoles or greens as may be required early in the summer. Transplanting all the cabbage tribe into nursery-beds is of great advantage to them; it renders them stocky and well rooted; and as this operation has for its object only the preservation of the plants during winter, it follows that a rather poor soil and open situation should be afforded them. It is of no use, however, to treat the Portugal cabbage in the above way; it is too tender to stand our climate, and therefore is better sown in spring in a moderate temperature, so as to be fit for final planting by the end of May. In cold, damp soils, we have found it of advantage to cover the surface between the rows of all newly-planted-out things, when the operation is delayed till too late a period, with finely-sifted coal-ashes to about an inch in thickness; they tend greatly to exclude the frost, and absorb a considerable quantity of humidity; besides, they render the ground comfortable and clean to walk upon. In many places where the crops are liable to be thrown out by winter frosts, tanners' bark is laid on the surface with beneficial effects. A good breadth should be planted by the first week in November, as little advantage would arise from planting again till the latter end of January. A supply of young plants for spring planting out should also, early in November, be removed from the seed-beds, and planted out in nursery-beds to stand the winter. In moist situations, the most open and exposed piece of ground should be chosen for this purpose, and, of all others, shaded and confined places should be avoided.

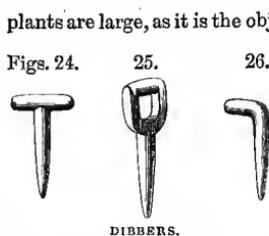

Under ordinary circumstances, the plants are set in their new *locale* by the dibber, of which

plants are large, as it is the object to remove them with as little check to their growth as possible, the planting-trowels, figs. 27 and 28, should be used. The dibber is too well known to require any description; the

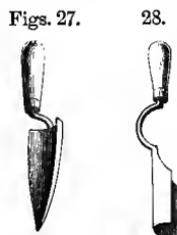

broken handle of an old spade forms one of the best kinds, which only requires to be cut to the length of 10 or 12 inches, and to have its perforating end bluntly pointed. The trowel is a more perfect implement, and is employed in the removal of plants of a larger size than can be safely planted by the dibber. In using either the pointed or semicircular trowel, figs. 28 and 29, the young plants may be taken up with a considerable ball of earth at-

tached to the roots, while they suffer no injury by the process. A more perfect mode of transplanting by the use of the trowel is that by taking two of these, one in each hand, thrusting them down on opposite sides of the plant, at the same time drawing the handles slightly outwards; the faces of the trowels are thus made to collapse so much as to press the soil about the roots, and hence enable the operator to take the plant, with ball entire, from the seed-bed to its ultimate destination, and to place it in its

new abode without the least check to its growth. As we shall have to refer frequently to transplanting, we may as well here show the construction of transplants, which have been long in use, for transplanting such crops as the Brassicæ, at present under our consideration. Fig. 29 is called Saul's Transplanter, because that intelligent horticulturist brought it into public notice many years ago in the pages of the "Gardeners' Magazine." It appears, however, to be an improvement on a similar implement invented by the Rev. Mr Thornhill, about 1820, and used by him for transplanting turnips. It may be thus described: The blades are opened by pressing the lever *a* towards the handle, when they open outwards, and in this state are thrust in the ground, having the plant within them; a counter pressure causes them to collapse, and to embrace the ball firmly, and in this state, the transplanter being drawn upwards brings with

DIBBERS.

TRANSPANTER.

it the plant and ball entire. It is then taken to its new site, set in its place, when the handle *a* is again pressed inwards, and the blades open and are withdrawn, leaving the plant and its ball entire, to be filled around with earth, and the

be pulled up without bringing the ball with them; or if so, that it may drop out during its transportation to its new site. The others we have shown are different; they collapse the ball firmly—and not only that, but by their construction they embrace it tighter

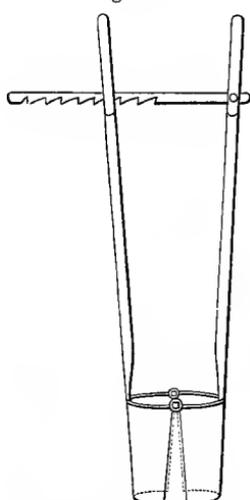

at bottom than at top, rendering it next to impossible that the ball shall be extracted, and also that it cannot slip out afterwards until relieved by the removal of the pressure upon it. Were the blades made in a tapering manner, then all the conditions of other similar transplanters would be fulfilled. All these transplanters are merely modifications of fig. 33, long used in France for similar purposes. Its principle will be readily seen by our figure: the handles *a a* are pulled outwards when the blades are thrust into the ground. They are pressed inwards when the operation of lifting upwards is desired.

Fig. 30.

TRANSPANTLER.

Fig. 31.

FRENCH  
TRANSPANTLER.

operation is repeated on another subject. Fig. 30 shows a modification of this implement, wherein the blades are opened by moving the slider *a* upwards, and, when thrust down around the plant, the blades collapse by pressing the slider downwards. The operation afterwards is the same as the last. Upon exactly the same principle, but with much more mechanical ingenuity, is the transplanter of Mr M'Glashan constructed, which is admirably adapted to such operations. Fig. 31 will explain its form; its mode of operation will be at once understood.

Fig. 32.

FLOWER  
TRANSPANTLER.

Fig. 32 represents another modification of transplanters; it is constructed of two semicircular pieces of iron polished to a bright surface, which all transplanters should be, because we know practically they enter the ground better, and deliver the ball more entire than they would do if used in a rusty condition. These semicircular pieces are furnished with handles *a a*, riveted to them, and are inserted into

the ground so as to enclose the plant between them. In this state they are attached to each other by two iron pins, passing through the eyelet-holes welded on their edges, *b b b*; on their being pulled up, the plant is elevated with its ball attached. Our objection to this implement is, that the radius of the blades, if we may so call them, is the same at bottom as at top, which renders it possible that they may

In planting all the brassaceous plants, drills should be drawn, 3 inches deep, at the distances apart which are to be allowed each variety; for amongst the tribe of early cabbage, to which most of our previous remarks apply, there are comparatively large-growing and small-growing sorts. The type of the former may be instanced in the vanack, and of the latter in Atkin's matchless. The ground should be prepared by heavy dunging and deep digging; but in this, as in all similar cases, trenching 2 or 2½ feet deep is better. The early sorts are set in lines from 15 to 18 inches apart, but Atkin's matchless, and one or two others, may safely be set at 12 inches only. The former should be from 1 foot to 15 inches distant in the line, while the latter may be set at from 10 to 12 inches. Plant, if possible, on moist days; if the soil is dry, run a good soaking of water into the drills previous to planting. Preserve the roots entire of those that have been transplanted into a nursery-bed, as every root is to them of importance. Those that have been drawn direct from the seed-bed should have the tips of the tap-root shortened, but none of the others.

The Scotch, late, or drumhead cabbage—for it is known by all these names—is seldom grown in gardens, unless where the bounty of the proprietor is, as it

should be, directed to the wants of the poor, by providing them during winter with soup made from the scraps which fall from his own table—then the drum-head cabbage comes in well; and also when *saur-kraut* is made for winter use, this vegetable is indispensable. It attains a very large size, and therefore requires room. At planting, they should be set in rows 3 feet apart, and the plants 2 feet distant in the line. This also depends on circumstances, for there are larger, taller, smaller, and dwarfier varieties of this kind. The above is the maximum distance.

*Subsequent culture.*—After planting, all that is required till they attain perfection is keeping the ground clear of weeds, stirring it frequently and deeply during summer, and drawing a little earth about the necks of the plants when about 9 or 10 inches high, which not only supports them in an upright direction, but offers opportunity for the roots to form near the surface, thereby increasing their means of collecting food, and greatly tending to encourage the more rapid growth of the plants. Some disapprove of the earthing-up plan, and as a substitute draw the drills deeper at planting, which seems to amount to the same thing. White cabbage is grown for three purposes, the first of which is to procure heads fully formed and hard, the second is to draw for use before hearting, and the third to furnish sprouts from the old stems for a long time after the head has been cut off for use. The first of these are called full-hearted cabbages; the second, cabbage plants or collards; the third, cabbage sprouts. To have them in the former state, they must be sown four or five times a-year. To have them in the second state, oftener; and in the third case, such as the vanack, an English variety, or McEwan's, a Scotch variety (the latter little known), should be selected. These, if planted in autumn or spring in good rich soil, will, after the first heads have been used, continue often for a couple of years sending up a fine and abundant supply of sprouts. When sprouts are not required, the old stems should be pulled up as soon as the heads are cut, and consigned to the rot heap. If left in, they greatly exhaust the soil for no end or purpose. Should any of the plants run to seed soon after planting, remove them

without loss of time, and replace them with strong plants from the nursery-bed, using one or other of the transplanters noticed above. Early in spring, when it may be wished to have close-hearted cabbages, as soon as the leaves give indication of turning inwards, tie the whole of them loosely together with strings of matting or slender twigs of willow. During long-continued droughts, water abundantly; and as all watering with pure water does little other than assist to render soluble the fertilising matter that may happen to be in the soil, and watering with spring-water does little more than chill the ground, and merely sustains the existence of the plants, it is better, seeing that there is the same labour in both cases, to water all growing crops with liquid manure. Water, however applied, is thought to injure the flavour of culinary crops. With the cabbage tribe it is the reverse, as they seem to be improved in flavour by it. It also prevents the plants from becoming stunted in growth, which induces a disposition in them to favour the production of aphides on the leaves, and other insects on the roots. The roots left in the ground after the heads are cut off, when the intention is to have a succession of sprouts from them, should have the remaining leaves cut off, the ground between the rows forked up, and if a good manuring be applied at the same time, the benefit will be evident in the greater supply, and its longer continuance fit for use. To make the most of the ground when the breadth is planted at the distances directed above for the larger-growing sorts, strong early-sown coleworts may be planted, either one or two between each two permanent plants, according to the space accorded them. These coleworts or collards will be useful to pull up for early spring use, before the principal crop arrives at its full size. When cabbages are cut, the leaves should be all removed from the stem, and all the embryo sprouts, excepting five or six of the best placed and most promising, to produce sprouts for table use. If all but one be displaced, it will grow rapidly, and soon become as large and fine as the original head. Such cabbages as have been cut during May and June will, by this treatment, yield another crop in July.

*Soil and manure.*—The first cannot be

too rich or too deeply wrought, and the latter can hardly be applied in too large a quantity. The whole tribe are gross feeders. The plant in its original state, as we have already shown, is a native of the sea-shore and of calcareous soils; it is consistent, therefore, with reason that lime and salt should be added to the natural constituents of the soil they are planted in. We have applied gypsum as a top-dressing to the surface between the rows, with the most beneficial effects, to all crops of the Brassica tribe, to which it seems admirably adapted. Its action appears to be directly and indirectly useful to such crops—directly as the food of plants, because, being soluble in water, it supplies sulphur and lime; and indirectly, because of its action on the volatile carbonate of ammonia, which becomes fixed when these substances meet. In the latter case, gypsum acts in the soil on the ammonia contained in rain water, in the same way as it does when applied to dunghills. A double action takes place between gypsum and carbonate of ammonia, when they meet in solution. Each of these salts being decomposed, their elements unite in the form of carbonate of lime and sulphate of ammonia, and the advantages from the change arise from the sulphate of ammonia not being volatile, as the carbonate of ammonia is. Stable-yard dung, if applied with gypsum to fix or retain the ammonia evolved from the former during the process of turning it over, and during the fermentation of the mass, will, in the case of rich manure, require to be used in the proportion of one cwt. of the latter to a ton of the former. Superphosphate of lime has been found a useful assistant to cabbage crops, and where manure is scarce it may be sown in drills prepared for them at planting, or a little (say a dessert spoonful) put in each hole before the root is introduced.

*Taking the crop, and subsequent preservation.*—When the plants have hearted, the heads are cut off for use, just as they begin to show the first indication of blanching towards the centre, which is undoubtedly the proper time; some, however, cut them in a more advanced state, preferring quantity to quality. Cabbage plants, collards, or coleworts—that is, young plants which are not intended to heart—are pulled up by the roots and tied up

into bundles, the roots being either washed or cut off to keep the leaves cleaner. Sprouts are gathered by being cut off the stems at various sizes and ages, from the time when they have only five or six leaves in size, until they form into little cabbages of the size of a swan's egg. It is in the intermediate stages, however, that they are most esteemed. It is seldom in Britain that artificial shelter is required for any of the white or red cabbage tribe. In cold places, however, they may be laid over on their sides, and their whole stems buried under ground. (Vide *Broccoli*, section 5.) The full-hearted cabbage is often cut from the stems on the approach of severe frosts, but it is better to retain the stems attached, and these are buried entirely in dry soil, and so deeply covered that the frost cannot reach them. They should, however, be placed so far apart that the one may not touch the other. In peaty soils, cabbages thus buried will keep for months, that soil containing so great an amount of antiseptic properties.

*Approved sorts of white cabbages (Brassica oleracea, var. Capitata) and their properties.*—The improvement that has taken place of late years in the whole of the Brassica tribe is perhaps greater than in any other division of culinary vegetables. Such sorts as Atkin's matchless, Sutton's imperial, Sutton's dwarf comb, Enfield market, Shilling's queen, &c., have taken the place in most of our best gardens of the sugar-loaf, early York, &c. of bygone days. These sorts are more esteemed for their delicate flavour and tenderness, when cooked at a proper age, than for their largeness of size—a merit only fitting for the lowest grade of market purposes. These require, in consequence of their small size, less space to grow in than the larger and coarser kinds, and will, nevertheless, yield as good a return, of the same extent of surface, as their larger allies.

1. *Sutton's dwarf comb.*—When grown along with other sorts, we found it last year the earliest of any. It is small, hearts well in spring, and affords a good supply of very delicate sprouts throughout most of the summer. It was planted 12 inches apart.

2. *Sutton's imperial.*—Another excellent early spring variety from the stock of Messrs Sutton and Sons, Reading; rather larger than the last, but equally early, tender, and useful, producing sprouts during the summer; planted 13 inches apart.

3. *Atkin's matchless.*—A small early cabbage of great excellence; conical when full grown; the leaves remarkably wrinkly, somewhat like a savoy; planted 12 inches asunder; stands the winter well; a variety of the early York, but much superior, if large cabbages are not required.

4. *Knight's early dwarf*.—A nice little hardy sort, which may also be set at a foot apart each way.

5. *Early Dutch twist*.—An excellent cabbage of the smallest size, very delicate, and may be planted almost as close together as a crop of cabbage-lettuce.

6. *Cattel's dwarf Barnes*.—A small early sort of great merit.

The above are the smallest and earliest of cabbages, and exceedingly well suited for small gardens and private family use. They should be sown more frequently than the larger-growing sorts, so as to keep up a succession of young and delicate heads, much after the manner of sowing lettuce.

7. *Early nonpareil*, *Shilling's queen*, *Shilling's superb dwarf*, *Tiley's early marrow*, *early emperor*, *early imperial*, are all equally excellent for second earlies and second-sized cabbages.

8. *Pomeranian cabbage* is thus described by Mr Thompson in "Journal of Horticultural Society," vol. v. p. 280:—"It is remarkable for its conical tapering form, very compact, and firm to the apex. It is very hardy, and may be cultivated like other hearting cabbages; but it may be interesting and useful to know that, at Macon, in France, the market-gardeners take it up out of the quarters when fully grown before winter, and lay it in the soil, to the neck, in a sloping direction. Thus treated, it withstood the severe winter of 1847. The quarter thus cleared can be trenched and prepared for other crops—an important advantage in small gardens. It is likely to prove valuable in colder situations than is suitable for the Battersea and other cabbages grown in the neighbourhood of London."

*King of the cabbages*, *London market*, *Wheeler's imperial*, *Vanack*, *Sprotboro*, *Paignton* or *Penton*, *M'Ewan's*, are all admirably adapted for general crops, where large returns are required. The Vanack has been cultivated above a century in the gardens of Colonel Wyndham at Petworth, Sussex, but it was only brought into general notice about thirty years ago. It has the merit of throwing out fine sprouts, which attain a large size for eighteen months or two years after having been first cut. M'Ewan's is of similar character, but of Scotch origin; it is difficult to seed, as it goes on sprouting and growing for almost any length of time. The Paignton is of Devonshire origin, named from a village of that name, where it has been cultivated for ages. Its properties are much the same as those of the two last. The Sprotboro is a Yorkshire cabbage, also of great excellence, in habit and properties much resembling the last four. The Paignton is also known in seed-shops as the Cornish, Pentonville, and curled.

To this section we may usefully add Chappell's colewort, which is little known out of the London market, where it is brought in immense quantities as an open green cabbage, being pulled before it hearts, and is sold as a colewort, and much esteemed. Colewort, cabbage-plants, and collet are synonymous terms, used for cabbages cut for use before hearting, and to be eaten in a young state.

The early York is probably the type of all our

best early cabbages, many of which, however, excel it in delicacy; no other sort is known to have the ribs and veins less prominent, which are its principal points. The Vanack is again the type of the imperial, Fulham, and Battersea. Of the Portugal cabbage there are two varieties, a taller and a dwarfier sort. The Pomeranian is very distinct from all others, is a good late sort, of conical form, almost terminating in a point.

*Approved sorts of Brassica oleracea capitata*, var. *Depressa*, De C.—*Large Drumhead*.—Known also as the Scotch, cattle cabbage, flat pole, and Strasburg. Of this there are several sub-varieties, differing chiefly in shortness of stem, concavity or flatness of head, &c. Of these De Candolle has recognised two distinct forms; viz., *Brassica oleracea depressa* (depressed or flattened drumhead), and *B. oleracea sphaerica alba* (spherical or great round Scotch cabbage). Those of dwarf habit are the best, as, being for winter use, they stand the frost better when close to the ground than when high above it. Unless, as we have already stated, a soup-kitchen is to be supplied, or *saur-kraut* is to be made, a small plantation of either of these varieties will be sufficient even for a large garden. In small ones, unless a head or two be required for pickling (and even for this purpose the red cabbage is preferred), we consider it the least profitable of the family to grow, as it is of little use after the head is cut off. It still occupies a place in most farmhouse gardens and cottages in Scotland, and frequently appears in our markets—an evident symptom how far we are behind our southern neighbours in the art of vegetable cookery.

The seed should be sown, in most parts of Scotland, from the middle to the end of August, and a strong rich soil should be chosen. In the warmer parts, and generally throughout England, it is better to sow in March, to prevent the crop coming into use too early in the following autumn, for this is to be regarded as a winter esculent. The autumn-sown crop is sometimes, if the plants are forward, planted out in the early part of November, but in general about the beginning of April following. Those sown in February or March should be transplanted in May, June, or July. Their whole routine afterwards is the same as for savoys or other cabbage. To have heads of a large size, plant at the distance of 3 feet by 2½; give abundance of liquid manure during their growing season, or, in default of that, fork in a good dressing of half-decayed rich stable-manure, using a fork for the purpose, of which Dr Yellowlee's, fig. 34, is a good example.

Fig. 34.

YELLOWLEE'S FORK.

*Dr Yellowlee's fork*.—Forks are preferable to spades for digging the ground, because, from their construction, the soil is much better

broken and pulverised, and the operation as speedily performed. They are much better when the ground to be loosened is occupied with the roots of trees or other plants, because less injury is likely to befall them. The entire length of this fork is 3 feet 3½ inches, the length of the handle being 2 feet 2 inches; the prongs are 7 inches apart at top, and 6 inches at the point; the length of the prongs, which are three in number, is 13½ inches, and at the top ¾ of an inch square, tapering to a point. The straps fixing the head to the handle are 11 inches long and 2 inches broad, and ½ an inch thick at the centre, tapering off at both sides.

## § 2.—THE PORTUGAL CABBAGE.

The Portugal cabbage (*Brassicæ oleracea*, var. *Oblonga*—Couve tronchuda, large-ribbed or Portugal cabbage, or Braganza) was introduced into England about 1821, from Trauxuda in Portugal, and is sometimes called Trauxuda kale. Of this there is a dwarf variety, much cultivated in Portugal, and known by the name of Murciana. This excellent vegetable, too little grown in Britain, is not exactly of the hearing kind. The centre leaves are deprived of their green or leafy part, leaving the ribs, which are boiled, and used much in the manner of sea-kale. It is exceedingly delicate, and in this respect different from the rest of the cabbage tribe. The dwarf variety Murciana (*Brassica oleracea*, var. *costata*, *chou de Beauvais*) is somewhat earlier, and throws out numerous suckers from the lower part of the stem, which the tall variety does not. It is much more tender than any of the others, and rarely stands our northern winters. For early crops, the plants should be sown in August, and kept under frames all winter, like cauliflower; or better, they should be, like it, sown on a slight bottom heat in February, and hardened off for transplanting in April or beginning of May. Its subsequent culture, &c., resembles that of cauliflower (*which see*).

[The most extraordinary production in the cabbage tribe is Kerguelen's Land cabbage, the *Pringea antiscorbutica* of botanists, first discovered by Captain Cook, the circumnavigator, and subsequently observed by Dr Joseph Hooker as a native of Kerguelen's Land, or Island of Desolation, situated in the centre of the Southern Ocean—a cold, humid, barren, volcanic rock, on which that distinguished naturalist recognised only eighteen species of vegetation, but amongst them this brassicaceous production. It is described by him in the "Flora Antartica" as very abundant, particularly close to the sea. Its root-stocks are from 3 to 4 feet long, and lying close to the ground, bearing at their extremities large heads of leaves, sometimes 18 inches across, and so like those of the common cabbage, that if growing in a garden they would scarcely excite attention. They form a dense white heart, that tastes like mustard and cress, but much coarser. It abounds in an essential oil, which renders it more wholesome than the common cabbage. It may never be worth the attention of the British cultivator, but its existence in that desolate island, so far

removed from civilisation as to be considered the most remote of all islands from any continent, suggests two important, although somewhat different, considerations. The first and most important is, that the Disposer of all that is good should have placed there a plant so valuable to those who traverse those little-visited seas, subject to one of the most fearful of all human diseases, scurvy, and that also presented to them the moment they put their foot on shore, where, from its luxuriance and abundance, it is likely, as Dr Hooker observes, to prove for ages to come an inestimable blessing to ships touching at this far distant isle. The next consideration is, how came it there? "The contemplation of a vegetable," he says, "very unlike any other in botanical affinity, so eminently fitted for the food of man, and yet inhabiting the most desolate and inhospitable spot on the surface of the globe, must equally fill the mind of the scientific inquirer and the common observer with wonder." A plant nowhere else recognised leads to the belief "that it was created, in all probability, near where it now grows—leads the mind back to an epoch far anterior to the present, when the Island of Desolation may have presented a fertility of which this is, perhaps, the only remaining trace." We know there is a theory recently promulgated, the adherents of which will account for the existence of this plant, in its unique form and isolated position, on the supposition that numerous centres of dispersion and new creations of developments exist, and that these do not in the slightest degree disturb the harmony of the general design of creation.

"One of the most mysterious of such phenomena is the change by which certain living entities seem to pass from the animal to the vegetable state, or *vice versâ*, without decomposition, or apparent disorganisation of fabric. Professor Von Esenbeck was the first to publish his opinions on the subject in 1814. His observations were made chiefly upon the filamentous algæ, particularly the Oscillatoria. The animal state is inferred from the spontaneous movements of the individual, the vegetable state from its immobility. A monad or active molecule issues from the summit of the filament, and frolics in the fluid in which the plant vegetates. Ultimately a period arrives in which a complete metamorphosis ensues, the moving monad being gradually converted into a motionless vegetable."

—The Rev. PATRICK KETH CLARK'S *Botanical Lexicon*, p. 264.]

## § 3.—RED CABBAGE.

Red cabbage (*Brassicæ oleracea*, var. *Capitata rubra*, De C.) Of this there are several varieties, differing only in their size, height, and colour. Medium-sized varieties are to be preferred, as also are low-growing ones, on account of their being less liable to sustain injury from frost during winter; but colour is of all the most important, as its chief use is for stewing or pickling, when a fine red colour adds much to its appearance. The sorts, or rather names, in the seed-shops, are, dwarf red, tall red, red pickling, early

blood-red, large red, drumhead, Dutch, and the Aberdeen red—a coarse, open-hearted half cabbage, half borecole, much grown in the North of Scotland, in cottage and farm gardens, on account of its extreme hardness.

The first and fourth are the best, if they can be procured genuine. They are sown, planted, and managed in the same way as the drumhead cabbage, noticed above, only, being of much smaller growth, they may at final planting be set at the distance of  $2\frac{1}{2}$  feet apart row from row, and  $1\frac{1}{2}$  feet in the line. On the approach of severe frost they should be taken up, and either buried in dry soil, or hung up by the roots in a dry airy shed, where they will keep for a long time. When the heads are cut, the roots should be immediately removed, as no longer of use, and to prevent exhausting the soil.

#### § 4.—BRUSSELS SPROUTS.

*Natural history.*—Brussels sprouts (*Brassica oleracea bullata, gemmifera*, De C., bud-bearing cabbage). Of this much-esteemed vegetable, introduced into this country from the Continent only of late years, there are only two varieties, a taller and a dwarfer grower, varying in height from 1 to 4 feet. The former is the most productive, on account of its greater length of stem, along the whole length of which the sprouts, like little cabbages, are thickly set. The latter stands the winter best. It derives its name of *chou de Bruxelles* from having been extensively cultivated around Brussels from time immemorial.

*Uses.*—It is used much in the way other cabbages are, being sent to table stewed, and as a garnish for butcher-meat, and at the best tables is presented, from the size of a large marrow-fat pea, which they indeed somewhat resemble, to that of their natural full size, somewhat under that of a pigeon's egg. The outer leaves being carefully removed, the hard, compact, little sprout is presented whole. Sometimes they are boiled, which is done with great care, using plenty of water, and that at the boiling point, when they are thrown in, adding a handful of salt, and leaving off the lid of the vessel. With the view of preserving their delicate green colour, they are covered with a rich stock sauce, in which vinegar and nutmeg form a part. They are also served boiled with white sauce, and in private families with melted butter. The quantity grown throughout the north of France, Belgium, and Holland is truly astonishing, whole fields of them being seen all over the country.

*Sowing and planting.*—Regarding their cultivation, they are sown early in April, and transplanted in June, into rows 2 feet apart, and the plants set 18 inches distant in the line. Their sowing, transplanting, &c., differ not from that of early cabbage: the same proportion of seed is also used. The soil, however, is in a different condition. If planted in soil as highly manured as that for other cabbage,

the sprouts would be produced coarse, large, and open, whereas the smaller and more compact they are the better. In Belgium, where an almost constant succession of sprouts is kept up, they sow on a slight hotbed in February, prick out on a warm border, and transplant towards the end of April. They afterwards make two or three separate sowings, at the distance of three weeks from each.

In England, for private families, two sowings are necessary—one in February, on slight bottom-heat, and the other in April. In Scotland, they often sow in August, and keep the plants over winter for spring planting, and again in March for a secondary crop. In the former, the first-sown crop comes into use in September, in the latter in November, at which time vegetation is moderated in growth, and the crop lasts till March; the second following in April and part of May, if the crop be taken up in February, and replanted to give it a check. By early and late sowing, and the superior advantage of climate, the Brussels market is supplied from the end of July to the beginning of May following. "The London practice," says Mr Cuthill, a high authority in such matters, "is to sow in May; but it should," he remarks, "be March. The Scotch sow them in August. Sown in May, it is impossible for the plants to get so tall, stout, and cover the stems so well with fine large sprouts, as when sown in March. I have had them," he says, "3 feet high, covered from top to bottom, each stem producing one peck of large close sprouts."

*Subsequent culture.*—The ground should be kept well stirred by frequent hoeing, not mere surface-scratching with a Dutch hoe, which, were it not for gravel walks, and that as seldom as possible, should be banished from gardens. The draw-hoe is better; and even that, beyond the mere cutting down of small weeds, which should not be allowed to appear, will be much better substituted by the Vernon hoe, fig. 3, or any of the modifications of it. When the plants are about a foot high, draw a little soil around their roots; and when about three parts grown, and while the sprouts are forming, the side leaves should be broken off, a few at a time, to give room to the sprouts to swell, and also that, by their removal,

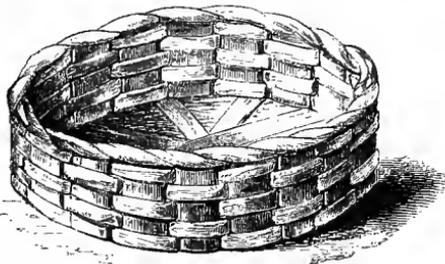

more of the energies of the plant may be thrown into them. It has been recommended to cut off the tops when the sprouts are fully formed, and this is a part of the Belgian practice. We prefer their retention, as from their form and position they protect the sprouts during winter from wet, frost, and snow. The top itself forms a useful vegetable after the sprouts are gathered, and, singular enough, possesses quite a different flavour from them. Many are deterred from cultivating this excellent vegetable, supposing it either too tender or less productive than a crop of cabbage, neither of which is the case. It is a plant calculated for simultaneous cropping, and may, therefore, be planted along with potatoes, placing the plants alternately in the rows.

“Select, if possible, a rich stiff loam for them; plant 18 inches plant from plant, and 2 feet row from row; keep the ground well loosened by the hoe. Moulding up the stems is never practised, and as soon as the plants reach their height, which is known by the top beginning to cabbage, *the latter ought to be cut out.* This throws all the strength into the sprouts down the stem, making the bottom ones as good as those on the top.”—CUTHILL, in *Market-Gardening around London*, p. 24. We have given reasons above for not cutting the tops off where danger is expected from frost.

*Taking the crop.*—When the sprouts have nearly attained their full size, they should be gathered for use, taking the largest first, and so on in succession, cutting them off with a sharp knife. When taken to the vegetable house (an apartment in all good gardens, where the vegetables are carried to be washed and dressed *fit for the cook*), the outer leaves should be neatly cut off; and if moderate care has been taken they need not be washed, as that would spoil their flavour, particularly if to be sent to a distance. When dressed, they should be put into a small punnet basket, fig. 35, which is made of thin split laths, and of various dimensions—from 3 to 6 inches deep, and from 6 to 9 inches in diameter, according to the sort of vegetable or fruit to be placed in them, and with or without handles, to suit various purposes. In such baskets all the most choice vegetables are carried, such as forced potatoes, kidney beans, Brussels

sprouts, mushrooms, &c. This is a branch in garden refinement that has, notwithstanding

Fig. 35.

PUNNET BASKET.

standing steam communication, not as yet reached Scotland. They can be purchased in Covent Garden for a mere trifle, and no garden should be without half a hundred of them at the least.

*General remarks.*—An unfounded prejudice exists against home-saved seed. Carelessly as much of this branch of horticulture in Britain is conducted, it is not much better on the Continent, at least where seed is saved for exportation. The case is different as regards that for home consumption. (*Vide SAVING BRASSICA SEED*, at the end of this chapter.) The safe way to save a pure stock, once obtained, is to propagate by planting the sprouts in spring after the manner of cuttings.

### § 5.—THE BROCCOLI.

*Natural history.*—The broccoli (*Brassica oleracea*, *Botrytis asparagoides*, De C.) The broccoli is of more recent introduction to Britain than the cauliflower, from which they are supposed to have originated. In Miller's time, only two varieties were known, the white and purple, and from these it is more than probable that all our present varieties have emanated. The white varieties of broccoli resemble the cauliflower much, only they are much hardier and constitute a winter vegetable, while the former is adapted only for summer and early autumn. The white varieties are in all respects preferable to the purple or other coloured sorts.

*Uses.*—These are as a substitute for cauliflower during winter and spring, when the other cannot be had in perfection.

*Mode of propagation.*—The same as the cauliflower, &c.

*Sowing and planting.*—The early varieties, such as the purple Cape, improved purple Cape, Walcheren, early white Cape, Grange's early cauliflower broccoli, and Gillespie's early, should be sown the first and second week in May for English practice, and a fortnight earlier for the Scotch climate, so as to have them in to succeed cauliflower, from the beginning of September

and onward till Christmas. Another sowing of the same kind should be made during the second week of June for the south, and not later than the first week for the north. These will stand over winter, and come in early in spring. Plants from the first of these sowings should be transplanted for good about the first of June, having been previously pricked into a nursery-bed, to give them strength and abundance of roots. Other varieties, of which there is a great number, should be sown about the second and third week in May for the south, and ten days earlier in the north; and, if transplanted about the middle of June, will, from their difference in growth, produce their heads during March, April, and May. As a general rule, calculating upon the kinds, for an autumn supply sow in April, for a spring supply in May, making an allowance of a fortnight between sowing at London and at Edinburgh, unless slight artificial heat in the latter case is had recourse to. The mode of sowing, the quantity of seed, and the earliest management are the same as for early cabbage (which see). Transplanting has been objected to by some as having a tendency to cause such early sorts as the white and purple Cape to button, as it is technically called—that is, to run up prematurely to flower, before the plant is sufficiently strong to bring the flower to perfection. And the means employed is to trench and manure the ground in May, to tread it firmly down, and to sow the seeds in lines 2 feet apart, dropping three or four seeds into each hole, made at the distance of 2 feet apart from each other. When the plants come up, they are all destroyed except the strongest, leaving one in each hole. The ground is kept deeply stirred during summer, and the plants are earthed up in the usual manner. The same mode has been recommended for early-sown cauliflower, lettuce, &c. We think careful transplanting preferable.

*Subsequent culture.*—This is the same as for early cabbage. The distance apart must ever be governed by the size of the variety—thus, for example, Knight's dwarf protecting will require only 18 inches plant from plant; while the larger-growing kinds, such as Elletson's gigantic late white, should be set 3 feet distant row from row, and the plants 2 feet apart in the

line. Much, however, in this depends on the soil and its state of cultivation. Deep stirring of the ground between the rows is all they require during the rest of the summer. It is only in very cold and damp localities, and in very inclement winters, that broccoli requires protection during winter; but it is advisable, with all the kinds intended to stand over till spring, to lay them over in November, which operation is performed by opening a trench at one end of the field, forming the back in a slanting direction, taking up the plants with as much earth about their roots as possible, removing two or three of the lower leaves, and setting them in the trench inclining towards the sloping bank, and covering up the roots and stems close to where the first pair of leaves issue. If the ground is much on the incline, begin at the lower part, so that the leaves of the plants may point downwards, to prevent the snow and rain settling in their hearts. This process not only prevents the weight of snow breaking down the leaves, but, by the check the plant sustains, causes the fibre of the leaves to assume a more tough and less succulent form by lessening the supply of food by the roots, and thus renders them less liable to injury from frost. In very unfavourable situations, the plants, when fully grown, may be carefully taken from the exposed part of the garden and replanted in the above manner in a more dry, warm, and sheltered place. It is, however, imprudent to set them in a damp or shaded situation.

When broccoli has attained its full size, which it will have done in most situations by the middle of November, the plants might be taken up carefully and disposed of as we have suggested (see *post*) for full-grown celery. This, in moderate climates, may be uncalled for, but in less favoured places it would secure their preservation, and at the same time clear the ground either for other crops, or for improvement by trenching, &c. In such cases the ridges should run in an east and west direction, the earliest kinds being placed with their heads towards the south, while the later sorts should have theirs in the opposite direction. This position would tend to accelerate the one and retard the other. A bank of broccoli thus arranged could easily be

protected on the top by a roofing of boarding, straw-thatched hurdles, or a tarpauling covering, which would ward off at once both wet and frost. Great care, however, must be taken in such a mode of protection that the plants be not crowded too closely together, else the want of a free circulation of air amongst them would be as disastrous to their safe keeping as if they had been left to take their chance where they were grown. As soon also as the heads are cut for use, the foliage should be instantly removed for the preservation of those that remain.

Laying in dry farm or stable litter between the rows, as high as the length of the stems, would protect the roots, but would afford no shelter to the leaves and hearts. Nor do we approve of Mr Knight's recommendation of transplanting in September, setting them deep in the ground with a view to encourage young roots from the stem to assist in swelling out the flower in spring. The late-flowering sorts will make roots when laid down as we have proposed, which will be in action during April and May, and no doubt will produce this effect. Those that flower before that period will have no such means of support, but must depend upon the sap already elaborated in the plant during the previous summer and autumn.

*Soil and manure.*—As we have said of cabbage, the soil can neither be too rich nor too deeply dug or trenched, the object in both cases being bulk of produce—unless, indeed, a very early supply is required, when a less luxuriant state in the plants may induce earlier maturity. All the Brassicæ are improved by lime, and to this may very safely be added a slight top-dressing of salt once or twice during their growth, the whole tribe being indigenous to calcareous soils, and in close proximity with the sea. Copious manuring with sea-weed, where it is readily procured, has produced excellent crops: a slight inquiry into the cause will lead us to view common salt as the stimulating ingredient. From experiments now in course of trial, we believe that flower of sulphur would be ultimately considered an excellent ingredient, not only as entering into the constitution of the plant, but as a preventive to the attacks of insects.

*Taking the crop.*—For the highest class tables broccoli should be cut when about

the size of a goose's egg, three heads forming a genteel dish. When for ordinary purposes, it should be taken when nearly full-grown, and before what is technically termed the curd is broken—that is, the flower opening—for on its firm and compact appearance much of its merit depends.

*Approved sorts and their qualities.*—1. *Grange's early cauliflower broccoli* is an old variety that, if procured true, still stands high in estimation, having a head nearly as large and as white as a cauliflower. The foot-stalks of the leaves are long and naked; the leaves somewhat ovate, slightly lobbed at the base, very slightly waved, and incurving a little over the flower, defending it from frost and wet. Not a large grower, and, being upright in habit, may stand at 2 feet distance apart. If sown in April or May, it will flower from the end of September till the end of December. Successional sowings of it should be made from April till the end of June. The London market-gardeners sow only four sorts, of which this is the principal, the others being the Walcheren, late London white, and the early purple or sprouting broccoli.

2. *Walcheren.*—Comparatively new; first produced by Mr Legg of Bishopsthorpe; so closely resembles cauliflower as to be scarcely distinguishable from it. The leaves are more curled than in the cauliflower, and its constitution is of a hardier nature, standing our ordinary winter in the open garden, and withstanding better the extreme droughts of summer. Mr Legg's practice in keeping up a constant succession is to sow the third week of April, middle and end of May, the middle and end of June, and the middle and end of July. For early spring use he sows about the 25th or 27th of August, keeping the plants through the winter under hand-glasses in the usual manner, leaving, however, only three or four plants under each glass. Of itself, by the above timeous sowings, it will become a complete substitute for all the others, and be at any time scarcely distinguishable from cauliflower.

3. *Gillespie's.*—A fine white early autumn sort much grown about Edinburgh; does not appear to be as yet much known about London. Treatment the same as for Grange's early. The same distance also.

4. *Early purple or sprouting*, attaining the height of from 2 to 3 feet; somewhat spreading; requires to be set 3 feet apart. Much grown by the London market-gardeners, and is much prized by French cooks, who dress the little sprouts in a variety of ways. The flower is close-headed, and of a fine purple at first, if the seed is genuine. It branches into sprouts afterwards, but is apt to lose its colour and become greenish, as well as to produce numerous small green leaves intermixed with the flower, if set in too rich ground. The London growers sow it along with all their other broccolis in May, when it comes into use in November, and continues all the winter, as fresh sprouts of flowers are produced from the *axe* of

the leaves after the head is cut. We sow in April to secure flowers in November. Sometimes a second sowing is made in June, which produces flowers the following April.

5. *Purple cape*.—A very early variety, the culture, &c. of which we have already noticed. The last two are almost the only purple sorts worth growing, and the five described the best of the very early varieties.

6. *Elletson's gigantic late white*.—One of the largest as well as latest white broccolis; dwarf on the stem; but, as the leaves spread considerably, it should be accorded 3 feet distance each way.

7. *Willcox late white*.—As large as the last, but hardly so late; grows taller, and requires the same space.

8. *Hammond's white cape*.—An excellent pure-white broccoli, flowering about December.

9. *Knight's protecting*.—If not so pure a white as the others, it possesses the great merit of being exceedingly hardy; and, being of very dwarf growth and small size, it may be planted 15 inches asunder, thus yielding a great return of produce off a small space, and therefore excellent for small gardens. Its heads are larger than might be expected from so small a plant. It is known from all others by a bracteal leaf, which is produced on one side of the flower as if it were designed for protection from frost and wet. It appears to be an improvement on the small green Danish, from which it may possibly have originated.

10. *Chapple's large cream*.—A very large and excellent variety, to which may be added Dilston's bride and Snow's superb white, two first-rate sorts. The latter is a dwarf variety, with broad leaves and short petioles, in size and colour resembling a fine cauliflower. If sown in the neighbourhood of London in May, it will come into use in November. If sown in Scotland in April, it will come in at the same time.

To those who require the hardier varieties, we would recommend the Siberian, late green, or Danish, which are all the same. It has been proved to be the hardest of any, coming in late in spring, when the slow increasing heat of the sun tends to swell it out to a fair size. The leaves are somewhat purplish, very much waved and indented; 2 feet apart is sufficient for it. The Russian dwarf is also equally hardy and small.

Besides, there are about thirty other varieties possessing less or more merit, and perhaps nearly half as many more names to be found in seed-lists, which are either worthless or possess similar or inferior merits to those in the above selection. They have been selected from about forty named sorts, which were grown within two years in the Dalkeith gardens.

The following broccolis are popular; their names, however, will suffice. Late dwarf purple Syrian, winter imperial, Dancer's pink cape, Adam's superb early white, Snow's winter white, impregnated white, Portsmouth cream-coloured, Sumner's late white, early Malta, Howden's purple, hardy green cape, American white, Tamworth white, Miller's dwarf, Stewart's early white, Addison's—the two latter much esteemed

about Edinburgh. Indeed, Stewart's early white and Gillespie's white are more grown by the market-gardeners than any others, coming in early in winter of a good white colour, and lasting till spring.

The true Walcheren, by successful sowings, may be had the whole year through, and, with Snow's superb white, Grange's early cauliflower, Knight's protecting, and Hammond's fine white cape, may be considered quite sufficient to afford a supply the whole season.

*General remarks*.—The difference between the broccoli and cauliflower is very slight. The colour in some sorts of the former is no doubt sufficient to mark the distinction; but amongst the finer varieties of the white-flowering kinds of broccolis, this distinction almost vanishes. Professor de Candolle, who has taken more pains to describe and systematise the order Cruciferae than any other botanist, has not forgotten to mark the differences which exist between them. He states, first, that both are varieties of each other, or rather varieties of the same race—*Brassica oleracea botrytis*, or cabbages producing heads or flowers of an eatable description, but of a very different organisation from the cabbage. From a very interesting paper upon this subject by that eminent botanist, published in the "Transactions of the London Horticultural Society," vol. v., the following brief extract is taken:—"The bunches of flowers, instead of being loosely spread into a pyramidal form, like those of a panicle, are close from their basis, and form a kind of a regular corymb; to which is added a second character, that may be considered as a natural consequence of the first: the pedicles, from being tightly kept together before their time of blossom, lose their shape, grow fleshy from adhering to each other, and in general produce nothing but the rudiments of abortive flowers; so that, contrary to all other varieties, where the leaves and stalks are alone taken for culinary purposes, in this the floral foot-stalk is the only part eaten. This race comprehends two varieties, viz., the cauliflower and the broccolis."

Their difference is thus shown:—"The *Brassica cauliflora* (cauliflower) has generally a short stem, white-ribbed oblong leaves, the pedicle uniting at the head of the primary branches into thick, short, irregular bundles, in the shape of a corymb; it appears to be a degeneration of the *Brassica oleracea costata*, or Portugal cabbage.

"The *Brassica cymosa* (broccoli); its stem is more elevated, the leaf-nerves less prominent, the pedicles altogether less thick and close; they are also longer, so that, on becoming fleshy, they resemble in shape the young shoots of asparagus: hence the name *Asparagoides* given by ancient botanists to broccoli. The broccoli seems to be a degeneration of some variety of the chou cavalier, tall or open cabbage. It is divided into two sub-varieties, the common or white broccoli, and the purple or Maltese broccoli; and each of these is again divided into several kinds by the practical gardener."

Cultivation, by improving the finer kinds of white broccolis, is narrowing the distinctive marks; but although so nearly alike, they must

ever remain distinct, inasmuch as they derive their origin from two very distinct types, namely, the Portugal cabbage, and the tall curled kale. The cauliflower originated also in the south of Europe—some say the island of Cyprus—while the other originated in the north of Europe, but whether in Germany or Britain we have no certain means of knowing. Others think the broccoli of Italian origin; and hence the older authors, in describing the then two only known varieties, call them *Brassica Italica alba*, the white broccoli; and *Brassica Italica purpurea*, the purple broccoli.

To obtain seed:—"Such plants of each variety must be selected in March or April as most perfectly agree with their peculiar characteristics, and are not particularly forward in advancing for seed. As the stems run up, some growers recommend the leaves to be taken away; but this must be injurious. Mr Wood of Queensferry is particularly careful that no leaves appear on the surface of the head. He always lifts his plants, and plants them in another bed, watering them abundantly, as this, he finds, prevents their degenerating or producing proud seed; and when the head begins to open, he cuts out its centre, and leaves only four or five of the outside shoots for bearing. The sulphur-coloured he always finds the most difficult to obtain seed from. As the branches spread, four or six stakes should be placed at equal distances round each plant, and hooped round with string to support them, and prevent their breaking. When the pods begin to form, water should be given repeatedly, and occasionally some thrown over the whole plant, which tends to prevent mildew. Before the pods begin to change colour, those from the extremity of every shoot must be taken away, as these yield seed which produce plants very apt to run to seed without heading, and by an early removal the others are benefited. The branches ought to be gathered as soon as the pods upon them ripen. Different kinds must never be planted near each other, or they will reciprocally be crossed. The seed ripens in August or September; and it is often recommended to preserve it in the pod until wanted, but the general practice is to beat it out as soon as it is perfectly dry."—*Cottage Gardeners' Dictionary*.

### § 6.—THE SAVOY.

*Natural History*.—The savoy (*Brassica oleracea bullata major*, De C.) has been known in Britain as a cultivated plant since the time of Gerard, who specially notices them, and ranks them amongst hearting or heading cabbages. It is sufficiently distinct from all these in the wrinkled leaves, which form its chief characteristic. The Brussels sprout is considered a sub-variety of this, but it is much more removed from it, in appearance, than the savoy is from the cabbage. It forms an excellent, bardy, and productive winter esculent, and is divided into two pretty distinct classes, the green coloured and the yellow.

Its use is the same as the cabbage, being used, when fully headed, during winter, and as sprouts

or collards, in some families, during most of the year.

*Propagation*.—It is propagated by seed sown annually, or by cuttings of the young sprouts in spring, after the head has been cut off.

*Sowing and planting*.—In many parts of Scotland these are sown in autumn, at the same time as cabbages, &c. are, for next summer's consumption. This, however, can only hold good in very cold and late localities. In others, the crop would be too forward, for they are not required in a full-hearted state before November. There are circumstances, however, when this is different; namely, where green savoy is required during most of the year, in the form of collards, like young cabbages. Sowing, therefore, to meet these demands, must be made frequently. (Vide *Early cabbage*.) For a general autumn and winter crop, a sowing towards the end of February, and another towards the beginning of April, will be sufficient, so that the plants may be set in their permanent position in May, June, or July. Half an oz. of seed will be sufficient for a seed-bed of 36 square feet.

The distances, &c. of the plants are in all respects the same as for cabbage, allowing those that are to be drawn as collards the same distance as cabbage collards, and those which are to remain to form perfect heads, from 24 to 26 inches between row and row, and 20 inches between plant and plant.

*Subsequent culture*.—An open and exposed situation is the best, beginning planting out as the young plants are ready in the nursery-beds; for it is important that they be removed from the seed-bed as soon as their leaves are about 2 inches in breadth. Choose the strongest plants for first planting, following up with the weaker in the course of a week or two, or as ground falls vacant from other crops. May and June is a good time for transplanting, when the crop is wanted during August and September, for southern practice; and the same time, or even towards the middle of July, for northern climates. The first, unless for market purposes, is perhaps too soon for English family use, as, during August and September, more desirable vegetables are in use. July and August are therefore a preferable transplanting season for

English consumption. In planting savoys, as well as any other of the Brassica tribe, observe if any of the young plants are clubbed or have knotty protuberances on their roots; if so, cut them closely off; but it is better to throw away such plants entirely, as they never make good plants afterwards. Soil has much to do with this clubbing, and it is found to be far more prevalent in poor gravelly soils than in those that are deep and rich. Savoys may be planted in the simultaneous mode of cropping; as, for example, between rows of previous standing crops, like pease, beans, early cauliflower, or the like, that are sufficiently advanced to be cleared off before the savoys will require the entire ground. The general crop will last in use from the beginning of November till the beginning of March, after which they will begin to run to seed, and should then be removed either to the rot-heap or the pigs, or be dug in as green manure for the succeeding crop.

*Soil and manure.*—These can hardly be too rich, and in a highly cultivated state. The same manures as for cabbage should be applied.

*Taking the crop, and subsequent preservation.*—In autumn, when the plants have attained their full size, and before they have become quite hard, they are fit for use, and in that state are more wholesome than when older; as all vegetable matter blanched white from deficiency of light is in a less fitting state as articles of food than when of their natural colour. In severe winters, the full-grown crops may be taken up and preserved as recommended for drumhead cabbage; and for prolonging them in a useful state till late in spring, the same means may be employed as stated for broccoli.

*Approved sorts and their qualities.*—1. *Dwarf green curled.*—A useful, hardy, smallish sort, fit for small gardens, requiring only 18 or 20 inches space each way. Excellent for use before it becomes fully cabbaged. Known also as small dwarf green curled, *pancalier de Touraine*.

2. *Cattel's green curled.*—An improvement on the last.

3. *Marcellin.*—A new variety of excellent quality, growing much larger than either of the above, and hence requiring more room on the ground.

4. *Cape, or drumhead.*—The largest variety grown.

5. *Globe.*—Very finely curled, grows taller than most others, yet not spreading in proportion. Known also as large green curled, large green, large late green.

6. *Dwarf yellow.*—Curled; differing from the dwarf green only in colour, which we think no recommendation.

7. *Feather-stemmed savoy.*—This curious and useful variety has been in existence for several years, being raised by Mr Barnes of Bicton, and is a cross between the savoy and Brussels sprout. Notwithstanding, we do not remember having seen it noticed in any seed-catalogue. It is what may be called a sprouting savoy, producing numerous sprouts along the stem. A sowing of it should be made about the middle of April, and another about the 10th of May, planting out as the plants are of fit size, in the usual manner of savoys and other winter greens.

From an excellent article upon the Varieties of Savoy, by Mr R. Thompson, in "The Gardeners' Chronicle," 1850, p. 244, being the results of experiments made in the gardens of the London Horticultural Society, we make the following additions:—

8. *Early green curled, or new early.*—Small outer leaves, rather plain, deep green; hearts readily, and is of excellent quality. It is considered the best for early use.

9. *Early flat green curled.*—Middle sized, very dwarf and flat headed, deep green, tender, and very good.

10. *Early dwarf green curled.*—Dwarf green, similar to the early green curled.

11. *Large green German, or large late green.*—"This," Mr Thompson says, "is the largest kind of savoy, and the best amongst the large. The leaves are plainer than in the other varieties; the head roundish, a little flattened, like a drumhead cabbage, which it also approaches in size. It is hardy, withstanding the frosts of ordinary winters well." This we apprehend to be the same as our cape or drumhead.

12. *Conical savoy.*—Rather small, pointed green, hardy, of very good quality, but affords much less weight of produce than several of the preceding sorts.

13. *Early yellow savoy.*—Middle-sized, roundish, yellow; hearts easily, of tender substance when cooked, and very good, but some object to the colour.

14. *Early long yellow.*—This, like the preceding, is an early variety, but it does not heart firmly.

15. *Earliest Ulm savoy.*—Described by M. Vilmorin, of Paris, in "Bon Jardinier," as being very dwarf, quickly forming a heart, which, though not large, is excellent. "It has been proved in the London Horticultural Society's garden, and stated by Mr Thompson as being the earliest in cultivation. It may be planted, in proportion to its size, considerably closer than the larger kinds." It is too small for market purposes, but in private gardens would no doubt be an acquisition.

It is somewhat singular that a long cultivated and popular vegetable like the savoy should have remained so long so true to its original character. Indeed, with the exception of the

feather-stemmed, scarcely any change has taken place for years.

### § 7.—THE CAULIFLOWER.

*Natural history.*—The origin of the name cauliflower (*Brassica oleracea Botrytis cauliflora*, De C.) is from the Latin *caulis*, a stalk, and *fero*, to bear; its original name being *coeleflorie*, or *coeleflorie*. It is first mentioned by Gerard, who says, "The white cabbage is next best to the cole flourey; yet Cato doth chiefly commend the russed cole; but he knew neither the whites nor the cole flourey, for if he had, his censure would have been otherways." From this it appears not to have been known in his day; subsequent Roman authors, however, mention it in such terms as to leave little doubt of its great antiquity, but of its origin we know nothing. Pierre Pompos, an old French author, says, "It comes to us in Paris, by way of Marseilles, from the isle of Cyprus, which is the only place I know of where it seeds." From this account Philips remarks, "It would appear that cauliflowers were not much cultivated in France in 1694, when his work was published; and the French have at present no distinct name for this vegetable, but call it *chou fleur*, or cabbage-flower."

*Uses.*—The heads or flowers are considered one of the greatest of vegetable delicacies when served up at the table, either plain boiled, to be eaten with meat, like other Brassicæ, or dressed with white sauce, after the French manner. It is much used as a pickle, either by itself or forming an ingredient in what is called mixed pickles. It may also be preserved a considerable time when pickled in the manner of *saur kraut*. It also forms an excellent addition in vegetable soups.

*Propagation.*—This is by seed sown at various times, for the purpose of keeping up a succession. It is scarcely capable of propagation by cuttings, and in our cold climate must ever be regarded as an annual plant; for keeping autumn-sown plants under glass, or otherwise protected during winter, does not constitute a biennial.

*Sowing and planting.*—Three or four sowings annually is the usual practice; but the seasons of sowing depend somewhat on circumstances, of which climate is the principal. The most prevalent practice, however, is to sow between the 18th and 24th of August; the plants of which sowing, when about 3 inches high, are transferred to a nursery-bed, and set about 4 inches apart. When sufficiently strong—which they will be by the middle of October—they are planted out in sheltered places, at the bottoms of walls, under hand-glasses, in cold pits or frames, in beds to be hooped over and covered with canvass, and sometimes they are

potted and kept under glass till spring, when they are planted out for good in the warmest situation the garden offers. These plants flower during May and June following. The second sowing is made about the end of February or beginning of March, on a moderate hotbed, the plants being finally planted out in April; but they should have the advantage of a nursery-bed, if only for a few weeks, to strengthen them. These produce flowers during July and August. The third sowing is made about the beginning of April, in the open ground; and the plants, after being pricked out in a nursery-bed, are finally transplanted in June, and will produce flowers from September until destroyed by frost. These are all important matters to attend to. Autumn-sown plants, if destroyed by frost during winter, may be replaced by others, forced upon hotbeds in spring, in time for the first planting; but a week's delay or advance in the third sowing may lead to the disappointment of either having the crop too early to supply the demand during October, November, and December, or it may be too late to flower at all. The above is the English practice, so far as dates are concerned. In most parts of Scotland, from the 1st to the 12th of August is the proper time for sowing the first crop, and a week in advance will be wise as regards the third. As for the second, as artificial means are employed, the exact date must ever be left to the discretion of the cultivator.

The London practice is to sow "the seed of spring cauliflower about the 20th of September, in open beds. Towards November, when the weather is beginning to get cold, frames and hooped beds are got ready in light rich land. The plants are pricked out not more than 4 inches apart each way: during the winter they are kept dry; no rain is allowed to fall upon them, but, whenever practicable, plenty of air is given to them. Frost has little effect on them under hoops; but when excluded long from air, and kept in darkness, they sometimes suffer from damp to a considerable extent. They are planted out in the richest and earliest ground, in February or the beginning of March."—*Market-Gardening round London*, p. 22.

Some of our best English gardeners

sow a fourth sowing about the middle of July, choosing a warm border, or throwing up ridges of soil and sowing the seed on the south side of the ridge, which ridges, of course, should run in an east and west direction. When the plants come up, they are thinned out to the distance of 9 inches or a foot apart, and allowed to remain without transplanting. In November nice little heads will be produced; and if not convenient to cover over the ridges with a roofing of boarding or thatched hurdles, as a protection from frost, the plants may be taken up and treated as noticed below. This late sowing seldom succeeds in Scotland, unless in warm, dry localities, such as along the shores of the Forth, where little rain or snow falls, and, from proximity to the sea, frost is seldom severe.

Half an ounce of seed is sufficient to sow a seed-bed of 36 square feet. Thick sowing should be avoided.

The method of sowing and planting is in all respects the same as for early cabbages (*which see*.)

The following ingenious method of keeping up a supply of cauliflower is communicated by Mr Henry Baily, of Nuneham Park, Oxfordshire, to "The Journal of the London Horticultural Society," vol. v. p. 103. Mr Baily is one of our most enlightened horticulturists; his method has both novelty and excellence to recommend it, and as his situation is not one of the warmest in England, similar success may attend those who follow his example. The true Walcheren sort only is used. "The first sowing for the spring crop is made about the 25th of August, and another, for smaller successional plants, a week later, upon an open border. As soon as the plants are large enough they are transplanted," that is, pricked out; "and as soon after that as they have made a few roots, they are again transplanted into small pots, called sixties: they are then placed in an open airy situation (either a frame, vinery, or peach-house, which is dormant), simply requiring protection from severe frosts; as they fill the pots with roots, larger ones are provided, and early in February the first crop, or handlight division, is planted out in a south border; the holes for their reception having received a barrowful of rotten dung, the mould is re-turned, form-

ing a little hillock, on which these plants are placed, and covered with the glass till they begin to be established. The smaller plants are reserved for a successional crop, potted into larger-sized pots, and placed in temporary frames, covered with mats in severe nights, but fully exposed in fine genial weather. This crop is generally planted out in the alleys of the asparagus beds, completes its growth before the tops of the asparagus become too high, and then has its duration prolonged by the shade of its branches.

"For the next crop in succession I sow in pots, about the middle of February, subjecting the plants to the same routine of potting, &c. Other sowings are made at intervals between this and the 20th of May, when the last crop is sown, which should be planted on a south border, for autumn use—extending up to Christmas, with protection.

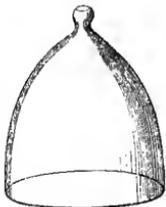

"For the February supply, an early white broccoli, grown by Mr Wilmot, of Isleworth, is invaluable. It is sown the end of May, and should be taken up and protected in a cool vinery, as our winters will not admit of the production of cauliflower at that season, as the fine climate of Naples does.

"The roots should never be allowed to get matted in the pots, or the plants to suffer any check. It will readily be conceded that our object in the cultivation of those culinary vegetables, whose stems, leaves, or flowers are eaten, is to grow them in the most rapid and luxuriant manner, avoiding any check at any period of their growth: any curtailment of those resources of plants which have a tendency to increase their luxuriance, and consequently render them more tender, must therefore, be detrimental, and it is to avoid checking the growth of the plant that the practice of potting is adopted. In dry weather, when the plants are drawn out of the seed-bed, and planted with a common dibber, receiving daily dribblings of water, many will perish, and all will be materially injured. By the mode I have described this is avoided, and labour saved in the end. After planting out, a copious watering is given, either in the evenings of bright days or in dull and cloudy weather, when it is not rapidly evaporated." Such a mode as this is well adapted to our northern climate.

*Subsequent cultivation.*—The safe preservation of the plants during winter deserves attention. They should be reared in an open, airy situation, and, when the leaves are about 2 inches in breadth, as we have stated above, should be *invariably* transferred to a nursery-bed, in an equally airy place, kept free from weeds and dead leaves, encouraged to make numerous roots, which transplanting considerably assists; for the stockier and stouter they are got to be, without being drawn up tall and slender, or of too gross and succulent habit, the better they will stand the winter. It is not, therefore, expedient to have the nursery-bed too rich, as this would induce them to send down naked tap-roots, and assume a degree of grossness that would ill enable them to withstand the frost.

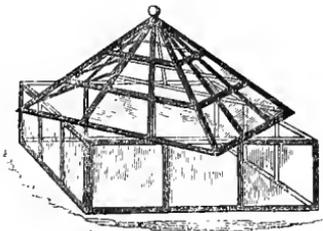

*Hand-glass protection.*—In October the hand-glasses should be filled, and those best fitted for the purpose are such as are constructed in pieces, so that the top may be removed entirely, or in part, on all favourable occasions, for the sake of ventilation, but more so to prevent the plants being drawn up or advanced farther than necessary. The glasses used for this purpose by the London market-gardeners are usually large bell-glasses, fig. 36,

Fig. 36.

CAULIFLOWER  
BELL-GLASS.

blown of green coarse glass, 18 inches in diameter and 20 in height, with a glass nob at top, answering the purpose of a handle. The better sort, however, is as shown fig. 37, and is made of cast-iron. The four sides are in separate pieces, and put together by projections at the corners, fitting into each other, and

Fig. 37.

CAULIFLOWER HAND-GLASS.

fastened by a wedge, and are each 20 inches square. Lead, zinc, wrought-iron, copper, &c., are the worst possible materials to construct such utensils with. Some substitutes for these have been proposed, but their utility verifies the old saying—"Saving at the spigot, and losing at the bung-hole." The cast-iron hand-glasses will last for fifty years, the others not as many months. They are glazed with the fragments of glass which abound in all gardens where hothouses exist. The manner of planting under hand-glasses is this:—In the best exposed place of the garden, dig out holes in number agreeing with the number of bell or hand glasses at disposal. These holes should be  $2\frac{1}{2}$  feet square, filled with one-half rotted stable-manure, and rather more than the other half the soil taken from the hole, so that the place, when finished, may be 4 inches higher than the surrounding soil. The hand-glass should be set upon this preparation to mark its dimensions, and five plants placed in each space—one in the centre, and one within 4 inches of each corner of the space.

These are to be regarded as the permanent plants, but, to secure as many more as can be, with a view to their being taken up in spring and planted elsewhere, six or seven more plants may be pricked in between them. The glasses are to be set at first over them, supported on four bricks, one at each corner, and, as the winter draws on, these are to be removed, and the glasses set on the surface of the ground, or rather pressed about an inch under it, the better to exclude the cold. Ventilation must now be attended to by lifting the top off entirely, or partially as shown in our fig., and only closing it entirely down when severe frosts exist. The bell-glasses are to be managed in a similar manner, only on good days they may be elevated on one side an inch or two, or entirely removed. Here the advantage of the hand-glass in pieces will be apparent. These glasses may be placed at 3 feet apart, which will afford sufficient room for each patch of plants to develop themselves fully when the glasses are removed in April.

*Wall protection.*—Those transferred to the bottoms of walls will, in general seasons, stand well, and, if thinned out in spring, the superfluous plants being transplanted

to an open part of the ground, will come in a fortnight or three weeks after those left to enjoy the reflected heat of the wall. In preparing the space for them at the bottoms of walls, which need not be more than 9 or 12 inches in breadth, no great fear need be apprehended of injuring the roots of the wall-trees, as these are, for the most part, progressing outwards. The soil may, therefore, be loosened up with a fork, and a good supply of stable-yard manure added, the plants set about 6 inches apart, to be afterwards thinned in spring to a foot distant. All the care required is to remove the leaves fallen from the trees, to dust the plants frequently for the suppression of slugs, and, in cold and damp localities, to cover the surface between them with finely-sifted coal-ashes to counteract damp.

*Frame protection.*—Plants for this purpose should be taken up from the nursery-beds: *the taking up* we consider essential, and much more than adequate to the saving of time which would result from placing the frames at once over the plants still growing in the beds. About the end of October or beginning of November transplant these into a bed of moderately conditioned soil, setting them 6 inches apart, so that the air may circulate freely through them. One precaution necessary in cold, damp, strong soils, is to elevate this bed 6 or 7 inches above the ground-level, to insure freedom from damp; cover with glass-lights at first till the plants take root, and afterwards, upon all occasions when frost or snow is apprehended, giving abundance of air at all other times. Cover the glass with canvass during severe frosts, keep the soil dry, and introduce between the plants, still further to insure this, an inch in thickness of finely-sifted coal-ashes; remove decaying leaves, pull up weeds, and leave till spring arrives, when more copious supplies of air must be given, and the plants gradually inured to stand the common atmosphere, when they may be transplanted out for good, which, according to climate, will be about the end of March or beginning of April, setting the plants in a warm place and in a highly-enriched soil, in rows  $2\frac{1}{2}$  feet asunder, and 18 inches plant from plant. In transplanting, remove with as much soil as possible about the roots, for which the

transplanters, figs. 29, 30, and 31, will be found useful.

*Wintering in pots.*—Where very early crops are wanted, and where there is fit accommodation, a set may be planted in 48-sized pots in October, and kept under a glass frame, cool peach-house, or the like, till February, when they may be turned out of the pots with their balls entire, and planted in a pit covered with glass in a richly-prepared bed, and there allowed to produce their heads or flowers. Cauliflowers, at so early a period of the season, will only be regarded by those who profess to distinguish a superior quality in the cauliflower over a fine well-grown broccoli, which, at the same season, will be in high perfection in the open garden. This we, however, know to be the case with some persons, and therefore, to provide for such a taste, it will be advisable to adopt the potting system.

*Spring-sown crop.*—Plants originated from seeds sown in February or March should be also transferred to nursery-beds to harden and gain strength; in these they should be allowed 6 inches apart plant from plant, to facilitate the operation of lifting with balls by the transplanter. About the end of April or beginning of May (all, however, depending on the weather, which, of late years, seems to put all nice calculations of this kind completely out of the question) they may be transplanted into the open quarter, setting them in lines 3 feet apart, and the plants  $2\frac{1}{2}$  feet apart in the rows.

The *summer-sown crop* is to be treated in a similar way to the last, and transplanted about the middle of July at the same distance as the last.

Throughout their season of growth the same management is required as already detailed for other Brassicæ, taking care that every one that begins to flag or droop its leaves, showing very evident symptoms of being attacked at the root, be taken up, and without further ceremony consigned to the nearest hothouse furnace, and, in default of that, to the nearest fire; for by this means such insects as are the cause of these disasters may be greatly limited in their future operations.

Some excellent cultivators contend that the middle of August is not the proper season for sowing, and that the whole

routine of wintering them, as usually is done, has a tendency to give unnecessary checks to the plants, and that it would be better to sow for early spring planting in the first week of October, on a very gentle bottom-heat, close to the glass, and to prick out the plants, as soon as they can be handled, into another bed, keeping them still close to the glass. This is the practice of Mr Barnes of Bicton, who says, in "Cottage Gardener," vol. vi. p. 309, "The last week in October and the first week in November they are potted into small 60's, and plunged under frame or pit lights, still close to the glass, and in due season they are again shifted as required into larger pots. At the beginning of January they get their last shift into 7-inch pots—that is, those intended to be turned out under hand-glasses the first week in February—but those plants intended to be grown on and forced in pots in some hot-house, are, of course, shifted into 10-inch or 12-inch pots; and those intended to be planted out into the borders and quarters are pricked into temporary shallow frames and turf-pits, in order to apply temporary shelter during the severe winter weather, by placing over them spare-lights, thatched hurdles, &c."

*Soil and manure.*—Much of the delicacy and excellency of the cauliflower depends on the quickness of its growth; therefore, to promote this, the soil cannot be too highly enriched, nor too deeply cultivated; and, as all the tribe thrive best in new soil, the deeper the ground is dug, and the more new or rested matter that is turned up for the roots, the better. Almost all highly-manured garden soils, if deeply trenched, will produce the cauliflower in great perfection; yet, in newly-broke-up soils, all the Brassicæ will luxuriate equally well even with a much more limited dependence on manurial applications.

*Taking the crop and subsequent preservation.*—The young heads or flowers are used when of the size of about 2 inches in diameter, and from that until they attain their greatest size, which may be taken as a maximum at 8 or 9 inches in diameter. It is not, however, size that constitutes the properties of a fine cauliflower, but its fine white or creamy colour, its compactness, and what is technically called its curdy appearance, from its resemblance

to the curd of milk in its preparation for cheese. When the flower begins to open, or when it is of a warty or frosty-like appearance, it is less esteemed; and indeed, when exceeding the size of about 3 inches in diameter, it is only fit for secondary market purposes. Nor should it, during summer, be cut above a day before it is to be used.

Towards the middle of November, should the weather prove severe, both late cauliflower and early white cape broccoli, then coming into flower, should be carefully protected. To this end the plants may be taken carefully up by the roots, and three or four tied together, and suspended with their heads downwards from the roof of some cool shed or outhouse, where there is not too much air, yet which is free from damp: strong currents of air would exhaust the sap from the plants too rapidly, and the flowers would become tough and uneatable, because the roots cannot now make up the deficiency. The leaves, after they have been hung up for a few days, and have become somewhat dry, should be folded round the flowers and secured by a string.

The best way, however, to preserve them during winter, is to take them up with as much soil about their roots as possible, and to replant them in light, dry, sandy soil in an open shed, where the accommodation of a regular structure does not exist. Figs. 676, 677, vol. i. p. 437, may be referred to as examples of such. In cool pits, frames, &c., they may be kept in a good state for many weeks; and even divesting the flowers of their leaves and burying them in masses of peat-earth has, from the antiseptic nature of such a soil, a very beneficial effect on their keeping. In mild localities, the mere breaking down of a leaf or two over the flower is found sufficient protection, as it wards off both wet and frost so long as the temperature does not fall above 4° or 5° below freezing: but in colder places it is necessary to protect them as we have stated, or by taking up the plants and laying them in by the heels—that is, replanting them in a slanting direction, and covering the roots and stems fully up to the middle of the leaves, in a sheltered and northern border, and covering them with branches and straw laid over them to throw off the wet, yet admit air,

or by any other means most convenient at hand. The drier, however, they are kept, under such circumstances, the better. They have also been kept for several weeks by being taken up when quite dry, the leaves folded over the flowers, and the whole buried in a trench in a dry soil. It is well in doing so to place them tops undermost, leaving a small portion of the roots above ground, which serves to draw them up by when wanted.

When the heads are cut and dressed for the kitchen, the stems should be cut off close under the flower, all the leaves removed, excepting two or three of the very young embryo leaves which are next to the head; these are dressed along with the flower, and make a better appearance on the table. If caterpillars are troublesome, place the flowers in a pail of clean water with a handful of salt for a couple of hours in the vegetable-house, before sending them to the kitchen. This will dislodge any insects that may have taken shelter within the flower.

It often happens that one or other of these expedients may be useful even for prolonging summer crops, when the one crop does not follow immediately that preceding it, or during dry summers, when the principal crops become likely to be exhausted before the next comes in.

*Approved sorts and their qualities.*—The cauliflower, unlike its ally the broccoli, has, by some not easily understood cause, remained pretty constant to what we may suppose was its original state. For long we had only presented to us in seed-lists the early and late cauliflowers. These, however, have had some additions made to them—if even only nominal ones, we may be thankful, seeing how we cultivators are beset with such long lists of names, as a reference to the articles PEA, BEAN, and BROCCOLI will abundantly show.

1. Early London white; 2. Early Dutch; 3. London particular; 4. Fine late; 5. Large Asiatic; 6. Large late German; 7. Walcheren; 8. Mercer's new pearly; 9. New dwarf late Cyprian; 10. Epps's superb; 11. Early cauliflower; 12. Early Leyden—are all names to be found in seed-lists. Concerning the merits of Nos. 3, 5, 7, 8, 9, 10, 11, and 12, Mr Thomson says Nos. 3, 8, 9, 10, and 11 appear to be all the same, and to these we have little fear in adding Nos. 1 and 2. He believes 1 and 12 to be identical with Legg's Walcheren broccoli. His conclusion is, that two varieties—namely, the large Asiatic and Walcheren—are found to be those most deserving of cultivation. The true Walcheren is distinguished from all others by its bluntly-rounded and broad leaves, and the closeness and almost snowy whiteness of its heads, even when grown

to a large size. It is most difficult to procure genuine seed of this variety. Those who are fortunate enough to procure it once should, if possible, save the seed themselves. For manner of doing so, *vide* end of this chapter.

## § 8.—THE SEA-KALE.

*Natural history.*—Sea-kale (*Crambe maritima*) belongs to the natural order Cruciferae, and Linnean class Tetradynia, and order Siliquosae. The name Crambe is derived from the Greek name for sea-cabbage.

Although of comparatively modern cultivation in Britain, the date of the introduction of this vegetable into our gardens is not correctly known. Mr Curtis states, upon the authority of Jones of Chelsea, that he (Jones) saw bundles of it in a cultivated state exposed in 1753 in the Chichester market in Sussex. Mr Maher, in a communication in the "London Horticultural Society's Transactions," vol. i., asserts that sea-kale was known in this country above 240 years ago; and that it was used by the inhabitants of the sea-coast as a common dish, is stated by both Parkinson and Bryant. The former flourished about 1629, which is the date of the publication of his "Paradisi in Sole Paradisus Terrestris;" the latter somewhere about 1783, when he published "Flora Dietetica." Strange as it may appear, sea-kale plants were sent from this country by Lobel and Turner, 250 years ago, to the Continent, where, at this day, in many parts, gardeners scarcely know it by name. It is now pretty common in the Paris markets, but we have scarcely seen it in any other; nor have we met with it in a cultivated state in any way approaching to what is seen even in the neighbourhood of Edinburgh, where its cultivation was attended to as early as it was in the neighbourhood of London. Mr Gordon of Fountain Bridge gives sensible directions for its culture in his "Gardeners' Dictionary," published in 1774; and Dr Lettsom, it is well known, only brought it into notice around London in 1767. In 1853, a comparatively small breadth of it is cultivated around our northern metropolis, while around our southern one some hundreds of acres are covered with it. Professor Martyn and Mr Curtis, by their publications, brought it into notice in England. In the south of Europe it is scarcely known; in the north it is only beginning to be attended to. Several young German and Danish gardeners we have had in the gardens at Dalkeith only recognised it as a botanical plant, never having seen it in a cultivated state. The same taste prevails in America. Our oldest English authority for any knowledge of this plant is Gerard, who gives its native habitats, but says nothing regarding its cultivation. It was known in the time of Pliny to the Romans, who called it *Halmrydia*; and although they do not appear to have taken it into cultivation, they used it as a sea provision during long voyages; gathering it where it grew wild, and cutting it up, they put it in barrels where oil had recently been kept, and these they stopped closely up, so that no air could reach the contents.

The sea-kale is a native of the sea-coast of Britain, as noticed by Gerard, who observes, in his "Herbal," that "the sea-colewort groweth naturally upon the beach and brim of the sea, where there is no earth to be seen, but sand and rolling pebble-stones." It is often found growing out of the crevices of the rocks even of our highest cliffs. When it grows lower down, it sometimes gets covered with sand, and thus becomes naturally blanched, which circumstance, no doubt, led to our blanching it artificially.

*Use.*—The young shoots and stalks, when from the length of 3 to 9 inches, are the parts used. These, however, unless blanched (etiolated), are no better than the coarser kinds of borecole, but when blanched they become exceedingly delicate, and much prized. The ribs of the leaves, even after they are nearly fully developed, are sometimes used, being peeled and eaten as asparagus. In either state they are tied up in small bundles and boiled, and served up with meat like cauliflower, covered with white sauce, melted butter, or on toasted bread. This kale cannot be too much boiled, so long as its form is not broken down; it should then be thoroughly drained, and set a few minutes before the fire, to allow more of the moisture to escape by evaporation, which renders it more crisp and better flavoured.

*Propagation.*—Being, unlike the majority of the Brassicæ, a hardy perennial, it is propagated by seed, and also by cuttings of the roots, which are replete with buds or eyes around the bottom of the crown, which are sufficiently visible; and also with dormant buds all over the surface of the roots, which are invisible, but will develop themselves if the roots are cut up into small pieces and planted. It is, however, in the estimation of some, best raised from seed, as such plants, at least for the first and second year, develop only one principal bud or eye on the top of the crown, throwing up a much stronger and better formed head than they do afterwards when several buds are allowed to expand. This, however, may be corrected by rubbing off the eyes when they have attained the size of large peas. The London market-garden practice is to propagate by the root in preference to the seed, and in the following manner:—"Towards spring, after the produce has been all cut, the roots are taken up; all the thongs," the long naked roots, "are cut off, and laid in large heaps; and as soon as the cut part or upper portion becomes hardened, ground is prepared for its reception by manuring and trenching. The roots are then planted out a foot apart, in rows 18 inches asunder, and a crop of

lettuces are planted between them: as soon as the buds become visible, all are cut out except the strongest one, the ground is kept clean, and nothing more is done till November, when they are ready again for forcing."

*Sowing or planting.*—Seed is sown in March; the roots planted at the same time. In cold damp soils, the beginning of April is better for the latter purpose; but much in this respect depends on the wounded parts of the roots being well healed over, else there is danger of their rotting. The seed is best sown in drills 2 inches deep and 6 or 8 inches wide, scattering the seed equally over the bottom to give the young plants more room when vegetation takes place. Some sow in beds in the broadcast manner, either of which will do equally well, as the plants are only to remain there for one season, when they are to be taken up and transplanted for good. Two ounces of seed will sow a bed of 36 square feet, or if in drills a foot apart and 8 inches in breadth, the same quantity will suffice. The seed is large and light, very often either too old or imperfectly formed; but this is easily ascertained by cutting them through the middle: if sound, the seed will be found plump and solid. They should be covered to the depth of 2 inches. Sometimes they are sown where they are to remain, in which case the same quantity of seed will sow a piece of 75 square feet in drills 2 feet apart, as it must in this case be sown thin. Care must be taken, when the plants come up, that they be thinned to the distance of 15 inches. Some divide the ground into beds, and set the cuttings or young plants in rows in them 2 feet apart, and the plants 18 inches in the line: when three rows are thus planted, a space of 3 feet is left as an alley, and another bed of similar dimensions formed. Others, instead of thin-planting the beds, make shallow holes along the line, and drop three or four seeds in each, leaving one plant only to come to maturity. Some people think that in this way the plants are stronger than when subjected to transplantation. For ourselves, having practised all the ways, we could never see much difference in the results.

The seed usually vegetates in four weeks. Mr Martin's plan of increasing sea-kale is

thus given by Mr Cuthill, in "Market-Gardening round London," p. 20. "At taking-up time"—that is, when the established roots are taken up for forcing, beginning in November, and continuing till the middle or end of February—"all the thongs are cut off from the plants. The small prongs or end roots are at once cut into 4-inch pieces, and laid together in a heap for the winter. In February they are deposited thickly in beds, and covered with mould an inch deep; when sprouted, it is seen by the buds which is the top, and by the roots which is the bottom. The ground being prepared, they are planted" as described above. "This last plan makes finer plants, as the whole of the strength is in the roots when cut off in winter, which is not the case after they have produced a crop. After forcing, the pores of the thongs must be empty, and they take a long time in recruiting." When seed has been sown the previous season, the young plants should be carefully taken up the March following, preserving their roots with the utmost care; they are then to be planted in richly-manured and deeply-trenched ground, in rows  $2\frac{1}{2}$  feet apart and 15 inches in the line, if the intention is to take them up the following winter for forcing. If, however, the crop is planted with a view to its remaining several years, either to be blanched where it grows, by covering with the sea-kale pot and the influence of the sun, or to be covered with leaves, dung, &c., and excited into growth during winter, then the rows should be 3 feet apart, and the plants set 2 feet apart in the row, to allow a full development of the large foliage during summer, for on this much of the success of the future crops will depend.

Fig. 38.

SEA-KALE DIBBER.

In planting seedlings, as the roots have very few fibres, they may be set with the planter, fig. 38, which is a wooden dibber  $3\frac{1}{2}$  feet in length, with a cross-handle at top, and another cross-piece as a gauge within from 9 to 12 inches of its point, made so as to shift to suit the length of the roots to be planted, which will in general average from 9 inches to a foot.

The lower part, which is to perforate the soil, should be  $3\frac{1}{2}$  inches in diameter, and tapering to 2 inches at the point, which should be left obtuse. The holes being made by one man using the perforator, and being guided by a line, another should follow, having the roots arranged with their tops all in one direction; and as the holes are made, he drops a plant into each, slightly filling in the soil about them with his foot as he progresses. From this it will be seen that propagation by the root is the most expeditious way, giving a saving of time equal to one season.

*Subsequent cultivation.*—Whether the plants are originated from seed, cuttings of the roots, or division of these, retaining the crowns entire, it is necessary that the ground around them should be kept clear of weeds, and also that it be repeatedly stirred up between the rows, and that not in the scuffling manner performed by the Dutch hoe, but well roused up by means of the Vernon hoe (fig. 3, page 38), care being taken that the extending roots be not mutilated. In spring, when the buds are beginning to break through the ground, and also once or twice during the growing season, a top-dressing of salt should be applied in quantity about 1 lb. to the square yard. The crop should be gone over in November in Scotland, and October in England, at which time the offices of most of the leaves will have ceased. Those that have changed to a yellowish hue may safely be removed as no longer useful, and this will admit light and air to assist the ripening of the buds. Where the beds are not intended to be destroyed, and the plants taken up for forcing, the ground between them should be forked up, and a good dressing of rich manure applied in which salt has been liberally incorporated. In this state the young crop, as well as those intended to be blanched without artificial heat, should remain till spring. Many recommend covering this crop with leaves or litter as a protection from frost—a recommendation wholly unnecessary, unless in some of the highest and coldest parts of Scotland, where such a precaution may be worth the trouble: for although the plant is a native of our own country, still its natural habitat is close to the sea, and never inland. What degree of frost

it may stand without injury has never been accurately ascertained.

A portion, however, of the crops should be covered early in November, so that it may be got readily at during winter, to take up for forcing. Some of the London market-gardeners grow their sea-kale for permanent crops in rows from 4 to 6 feet apart, and in autumn, after the foliage has fallen off, they cover the crowns with soil dug from the alleys to the depth of a foot or 15 inches, by which means they procure it finely blanched in spring, and at little expense. As soon as this crop is cut, they level down the ridges, and crop with other things between the rows. Remove every flower-spike as it appears, for the production of seed is much harder upon the energies of the plant than taking a crop from it.

*Soil and manure.*—In a cultivated state, sea-kale does not appear to be very particular about either, succeeding in most, provided the former be sufficiently deep and dry at the bottom, and that the latter be rich and incorporated with saline matter. Deep treuching where the land will admit of it is important, and where that is not naturally the case it may be rendered so by excavating broad alleys between the beds, and elevating them with the material taken out.

*Forcing.*—From the middle of November till it comes into use in the open air, this vegetable may be had in great perfection, at a season when other choice vegetables are scarce, and this at little trouble or expense. In former practice it was recommended to force the crop in the ground on which it grows; than this there can scarcely be a more unsatisfactory, uncertain, and expensive process recommended. The objections we should state are, the waste of manure in producing the necessary heat by fermentation, the waste of time in carrying in and out, turning over and adding to the material, the uncertainty of the heat produced, the expense of blanching-pots, open wooden cages, or whatever other means may be used to separate the fermenting material from the crowns of the plants; the deterioration in flavour, the trouble in examining the state of the crop and of gathering it, and lastly, the injury inflicted on the plants by keeping them so long in a state of excitement. To

avoid much of all this, and at the same time to insure a certain return within a given time, the best method is to adopt the lifting or taking-up process. To prepare the plants for this, forms, as in the case of taking up asparagus, an important element in the rotation of crops. Plants should be grown for the special purpose: a seed-bed should be sown annually, from which to transplant the young plants in March into lines, in ground deeply trenched and abundantly enriched, setting them 3 feet apart row from row, and 15 inches in the line. If these are stimulated abundantly during the season after planting, care being taken that they do not form flower-stalks, and that all lateral buds are displaced as they appear on the sides of the main stems, throwing the whole energy of the plant into the centre bud or crown, the roots will be in excellent condition for taking up for forcing as soon as their buds are fully matured, and the foliage has died away, which with us, in general, is about the beginning of November. The roots should then be carefully taken up, carrying with them as many of the small fibres as possible: soil is of little consequence, except in so far as it may be conducive to the preservation of the roots. For although these are not much required for the natural purpose of collecting food for the plant, under the treatment to which they are to be subjected, they are valuable, inasmuch as they, along with the bud and stem, contain the elaborated matter formed during the past summer, and hold it in store for the formation of the shoots and leaves, which the excitement of a moderate temperature and slight humidity will call into action. The best situation in which to place the roots is on the floor of a regular mushroom-house, or, in the absence of it, the floor of a cellar, outhouse, or enclosed shed, into either of which a slight temperature can be thrown by means of a hot-water pipe or otherwise. The advantage of such places is, that while the necessary heat can be applied, light may be sufficiently excluded to insure blanching, while air to a certain extent is admitted, which is of no small consequence to the crop. In such places also the progress of the crop can readily be ascertained, and the gathering effected with facility. It matters little what the soil is

in which the roots are set; they derive no benefit from it further than exclusion from light and air, and being kept in a state of uniformity as regards moisture. This we apply pretty copiously by watering the roots and soil with tepid water, though others object to watering after the roots are arranged. In placing the roots, they are set closely together, and the soil is wrought regularly in amongst them, and up to within 2 inches of the tops of the crowns. Some, where the demand is not very great, place the roots in boxes or large flower-pots, which they place in any dark and out-of-the-way place; and in this way we have seen as fine blanched sea-kale at Christmas, in a wine-cellar in the city of London, as we ever saw in any quarter. Under the stages in plant-houses, behind the flues in early vineries or peach-houses, or, indeed, wherever there is a vacant square yard of space, this vegetable may be produced in perfection. We state these simple means, because they are within the reach of most or of all, and also with a view to get rid of the waste of time and material by attempting to produce it in the open ground. From five to six weeks will be required between the time of setting in the roots and gathering a dish, in places without any artificial heat; in such as have a uniform temperature of from 50° to 60°, the time will range from two, three, to four weeks, sometimes less. It is, however, best to allow excitement to go on very slowly, as the shoots will be much finer and stronger. When the crops are gathered, the old roots are thrown away. Those, however, which have been forced latest may be cut up into pieces of 3 to 4 inches in length, and planted in lines to produce a succeeding supply. Young seedling plants are, however, much preferable.

The practice of the London market-gardeners is thus described by Mr Cuthill: "When all the frames are removed, the dung and mould where cucumbers grew during summer are taken away, the trenches, which are 2 feet deep, are again filled with hot dung, and mould to the depth of 8 inches is put on the dung. The sea-kale roots are dug up, all the small buds round the main eye are pared off, leaving that by itself, which induces it to push stronger and finer. And now planting is commenced: a furrow is cut

out by the spade across the bed, and they (the roots) are put in as thickly as possible. 5 feet across will hold from twenty-five to thirty roots; the next furrow is cut out at 4 inches from the last, and so on till the whole is finished; from 4 to 6 inches of straw is placed immediately on the crowns. The beds are hooped over, and straw is put over the hoops; and in this way I have seen 50,000 plants forced during the winter and spring, and that by one man alone." If we calculate that five heads are quite ample for an ordinary dish suitable to a large family, this grower must have himself provided no less than 10,000 dishes of this excellent vegetable by artificial means, and probably double that number from the open air. Such data will give some idea of the production and consumption of a London market-gardener.

Forcing the plants where they grow requires from six to seven weeks from the time they are covered up until the crop is fit for gathering. This, however, to some extent depends on the season and the quality of the fermenting material; and to effect this in the best manner, trim off all the decaying leaves from the plants, stir the surface up slightly around them, sprinkle about a teacupful of salt or caustic lime around the crowns, or water with lime-water to banish the earth-worms, *Lumbricus terrestris*, L., which are apt, upon the application of heat, to throw up their casts about the young kale, and thus render it very dirty. The same means secure the buds from the attacks of snails, *Helix aspersa*, and slugs, *Limax agrestis*, L., the milky-slug, *L. ater*, L., the black slug; *L. Maximus*, the black striped slug; and *Testacellus scutulium*, the shield slug, which are all apt to feed upon the young buds, and certain to gather round them in consequence of the genial heat. Over either of these a spadeful of clean river or sea sand should be placed, or, in default of these, a spadeful of finely-sifted coal-ashes, either of which keeps the young kale quite clean and fit for use.

The sea-kale pots should then be placed over them, one pot to a plant, and over these the fermenting material, to a depth sufficient to raise a fine genial temperature, not, however, exceeding around the pots 60°; less will do.

The best kind of sea-kale pot is that represented by our fig. 39; it consists of two parts—a body, *a*, and a top, *b*—which latter is necessary, as it can be taken off to examine the state of the crop, and also

SEA-KALE POT.

to gather it without having to remove the whole of the material. They are of various sizes—from 10 to 14 inches in diameter, and from a foot to 20 inches in height. There are other contrivances to effect a similar end, such as boxes perforated with holes, others made of 2-inch laths nailed together, and about as far apart from each other, the top ones being left loose for lifting when the crop is to be gathered. Reason points out the defects of these, as they do not exclude the moisture, accompanied with various gases, which are evolved during fermentation of rank stable-yard litter, and which, in many cases, communicate a disagreeable flavour to the kale.

Amateurs may readily force sea-kale, if they have any dark warm cellar or out-house, or one that can be heated to something like 55°, in the following manner:—Procure an old cask or a large packing-box; perforate the sides of either with holes 2½ inches in diameter, and about a foot apart, making the first row of holes a foot from the bottom. Procure the roots; divest them, if large, of a few of their most extending roots; place them in the bottom of the cask or box, with their crowns exactly opposite the holes: when the first row is thus arranged, pack the roots around with sand or soil of any description, and work it well amongst them; over this arrange another set of roots in like manner; proceed till the box or cask is full. Give a gentle watering with tepid water as the process of packing proceeds. In the course of a fortnight, three weeks, or a month, according to the heat in the apartment, the young buds will begin to protrude through the holes, and in another week or so many of them will be fit to cut for use.

As a general rule, avoid a high temperature, whatever method is followed; from 55° to 60° is the proper heat to secure a certain return.

*Taking the crop.*—When the kale is from

3 to 6 inches in length, it is then in the most proper state for use. Each bud should be cut off with a sharp knife, taking about a quarter of an inch of the crown attached to its base to keep it together in compact form. This portion of the old crown is to be neatly pared down close to the part where the young sprout springs from, the kale dipped in clear water to remove any dust that may have attached itself to it in the process of gathering, and then be placed in a punnet-basket, of which fig. 35 is an example. If to be sent to a distance, it is best tied up in small bundles, which prevents the tops from being broken. From four to six buds make a dish. Three stout plants will produce about five dishes in a season when forced, and an ordinary managed plantation in the open air will continue in bearing about six weeks.

There is only one variety known.

## § 9.—THE BORECOLE.

*Natural history.*—Borecole (*Brassicæ oleracea sabellica*, De C.), a family of the Brassicæ tribe both useful and numerous. The chief characteristic of the borecoles is that they are open-headed, not hearting like the cabbages, nor producing eatable flowers, like the cauliflower and broccoli. They are for the most part extremely hardy, and we entertain a strong notion that some of them are very early removes from the *Brassicæ oleracea* in its wild state. Some of the sorts are much cultivated in the north of Scotland, a circumstance arising from their hardy constitution, for, deprive them of that, and those varieties to which we allude have not a redeeming quality—ill-coloured, coarse, rambling-growing subjects, requiring long boiling and a strong digestion. Prejudice, we believe, continues the cultivation of those over that of one of the very best of the family, the German greens or Scotch curlies, which we believe to be equally hardy. They all belong to the same natural order, to the same class and order in the Linnaean arrangement as the rest of the esculents comprised in this chapter. Borecoles, in one shape or other, are cultivated in every country where attention has been paid to the rest of the Brassicaceous esculents.

*Uses.*—The crown or centre of the plant is cut out towards the middle of November, and continues to be used throughout the whole winter, while in spring numerous small delicate sprouts are formed, which are acceptable at that season. When properly cooked, they are tender, sweet, and delicate, and are by some supposed to become intenerated after being exposed to the frost. The coarser sorts may be thus improved, the better sorts do not require

it. The young tops of the Buda kale are sometimes, in spring, blanched by turning a flower-pot over it; or better, by placing a sea-kale pot on it; or the roots may be taken up any time during winter, and planted in a bed of soil in a dark cellar, and treated as has been recommended for sea-kale. The bulbs, like turnips, found on the surface of the Egyptian kale or kohlrabi, are stewed, boiled, and mashed like turnips, and sometimes sliced in some German salads. The tender tops of the others are served to table plain boiled, as a garnish for meat, and should assuredly accompany it in the popular Scotch winter dish "beef and greens." They enter largely into soups, and form an ingredient as essential in the national dish, "the kail-brose of old Scotland," as horse-radish does in that of "the roast-beef of old England." Scotch greens are often mashed with butter and pepper, and served in imitation of spinach, and, like it, garnished with hard-boiled eggs.

*Propagation.*—Most of the varieties, being annuals or biennials, are propagated by seed; those that are perennial or half shrubby, like the Woburn kale, are increased by cuttings, and some may be grafted on other sorts, (*vide art. PROPAGATION BY GRAFTING*). One ounce of seed is sufficient to sow a bed of 40 square feet.

*Sowing.*—The latter end of March, in April, the first week in May, and lastly, about the 12th of August, are the seasons adapted to England; for Scotland, generally ten days earlier in each case. For the most part, however, those sown about the beginning of August, in the North, stand over winter, and are transplanted in spring. The English sow German greens, or, as they call them, Scotch kale, during the first week in April. In the last week in August a sowing is made of Buda kale, to be transplanted before the 1st of October, to furnish a late crop of greens in spring.

The method of sowing, &c., is the same as for savoys (*which see*).

*Subsequent culture.*—The same as for savoys. In all cold exposed places, and where much snow is expected, it is expedient to lay them over in November, as recommended for broccoli, as their leaves are very liable to become broken by the weight of snow, particularly the taller-growing kinds.

*Soil and manure.*—The borecoles being of less luxuriant habits, and it being also desirable that they should stand the winter, the soil need not be so highly manured as for the other varieties of Brassicæ. Where the ground is not re-

quired for other crops or purposes, they may be made to succeed the summer pea crops, and, indeed, if ground be scarce, may be planted between the rows of late pease, or interlined with potatoes.

*Approved sorts and their qualities.*—Great confusion exists in this section of the Brassicæ, probably arising from the circumstance that the cultivation of them is for the most part local, those that are grown in one part of the kingdom being almost unknown in other parts. Although we have been engaged for some years proving various sections of culinary vegetables, we have not as yet had time to bestow the same attention on the present section; and rather than mislead, we shall quote the substance of an excellent paper by Mr Thompson, being the results of his experiments carried on in the garden of the Horticultural Society of London, where an immense number of sorts by name were grown together, to enable him to draw the conclusions regarding their nomenclature and merits; and certainly to no one better qualified could such an experiment have been intrusted. Mr Thompson begins by observing that "the varieties of these are endless: they differ in having stems dwarf or tall, leaves more or less cut or curled; in colour, green, purple, or variegated with purple, red, green, and yellow. The transformations of all these render any attempt to give minute descriptions quite useless. It will be sufficient to point out the general characters of varieties that may be usefully distinguished as such.

"*Dwarf green curled*, or dwarf curled kale, dwarf German greens, very dwarf green curled, dwarf winter curled, Scotch kale, green Scotch kale, dwarf curlies, French dwarf curled, Canada dwarf curled, Labrador kale, green borecole, and dwarf green borecole. By one or other of the above names this is certainly known to every one. The Canada dwarf curled was found to represent exactly the finest dwarf curlies grown many years ago in many parts of Scotland, the plants being very dwarf and closely curled.

"*Tall green curled*, or tall German greens, tall Scotch kale, tall green borecole, and tall greens," with a host of French and German synonymes, for in both countries they are extensively cultivated. "Height usually from 2 to 3 feet, but 2 feet is the preferable growth. The plants are capable of bearing severe frost, and, like the preceding, it affords the best greens from the time when the first frost has mellowed its flavour, until the middle of February.

"*Purple borecole*, or purple or red borecole, tall purple kale, purple winter greens, brown kale, purple kale, curled brown kale, curled red kale. This in its formation and habits differs little from the tall green curled, but the colour is deep purple. As the leaves enlarge, they have an inclination to become green, but the veins still retain the purple hue.

"*Variegated borecole*, or variegated kale, variegated plumage kale," with various French and German synonymes. "A sub-variety of the purple borecole, having the leaves beautifully

variegated, sometimes green and yellowish white, green and purple, bright red, purple and green. It is occasionally employed for garnishing, but it is very good cooked after frost. It is not quite so hardy as the purple borecole.

"*Dwarf purple borecole* and the *dwarf variegated* are merely sub-varieties of the two preceding, distinguished by their dwarfer habit of growth.

"*Buda kale*, or Prussian kale, Prussian or Buda kale, Buda greens, Russian kale, Hamburg kale, Anjou kale, Manchester kale, asparagus kale, Duke of York's kale, Camberwell kale; and so closely allied as not to be worth distinguishing from it are, the Jerusalem kale, Delaware greens, Delaware kale, ragged Jack, jagged kale, and the dwarf feathered kale. The Buda kale is not so tall as the purple borecole; very hardy; leaves purplish, somewhat glaucous; cut and fringed.

"*Woburn perennial kale*.—This is a tall variety of the purple borecole, with foliage very finely divided and fringed. The plant lasts many years, and may be propagated by cuttings, as it neither flowers readily nor perfects well its seeds. Its produce at Woburn is stated to have been more than four times greater than either that of the green or purple borecoles, on the same extent of ground. The weight of produce from 10 square yards was 144 lb. 10 oz., but some of the large kinds of cabbages and savoy's will exceed this considerably, and prove of better quality. The Woburn perennial kale can, therefore, only be recommended where the climate is too severe for the more tender kinds of the cabbage tribe.

"*Tree cabbage*, or great cow cabbage, Cesarean borecole," with many French and German synonyms. "This grows to the height of 6 feet, and in La Vendée and Jersey it is reported that it attains the height of 12 feet and upwards. The leaves are large, smooth, or but slightly curled; its sprouts are said to be good when cooked. Its merits have, however, been greatly overrated, for when tried [in England] against other cabbages, its produce was nothing extraordinary.

"*The thousand-headed cabbage* is allied to the preceding, but does not grow so tall, and sends out numerous side-shoots. On the whole, it is preferable to the tree cabbage.

"*Flanders kale* is a tall-growing kind, distinguished from the tree cabbage by its purplish foliage.

"*Cockscomb kale* produces sprouts along the ribs on the surface of the leaves, but it is of little value."

To these kales we may add the imperial hearting or cabbaging kale; and we believe the German cabbaging borecole of some seed-lists to be the same. It appears to be a sub-variety of the dwarf green curled, dwarf in growth, the leaves standing nearly upright, turning in slightly towards the centre, finely curled, and of great excellence as a small delicate variety.

"*The palm borecole* is a tall rambling kale of no estimation in Britain. It is cultivated in many gardens in France under the name of Chou Palmier.

*The Chinese cabbage* (*Brassica chinensis* L.),

although recognised as a species by botanists, has much the appearance of being connected with both the cabbage and the turnip. It is an annual of rapid growth, for, if sown at midsummer, it will ripen seed the same season. It is cultivated in some of the gardens around Paris, and has been tried in the Horticultural Society's garden at Chiswick; the results, however, lead to a belief that it is not suited to the climate of Britain.

"*The khol-rabi*, or turnip-rooted cabbage (*Brassica oleracea Cavolo-rapa communis* De C.)—Of this there are two varieties, the one having the turnip-shaped bulb, of a pale-greenish colour; the other of a purplish-plum colour. The plant is of low growth. The part chiefly used is a turnip-looking bulb, formed by the swelling of the stem, which is short. It is extremely hardy, and much grown in the north of Europe, where the bulb is dressed whole, and eaten with sauce or with meat, as turnips usually are. The seed should be sown on a warm border in February or March, and planted out when the plants have attained the height of 6 or 7 inches. For successional crops, sow again in April and May; the latter will produce plants for winter use. It should be eaten while young, as it becomes hard and stringy, and does not boil soft if left to become old.

*Diseases and insects*.—Amongst the diseases that affect the brassicaceous tribe is the white rust, called by many the mildew, perhaps on account of its white appearance. The white rust is even more formidable than the mildew. Both are fungi, and although deriving their origin from nearly the same causes, are different in their botanical as well as their injurious distinctions. The common white rust (*Cytopogon candidus* of Greville, *Uredo candida* of Persoon) produces a white leprous appearance on the leaves of the plants. These white patches of parasitic fungi not only disfigure but materially injure the plants, as all parasites must do, whether of vegetable or animal origin, because they derive their very existence by exhausting the energies of the plant. Again, there is the *Botrytis parasitica*, which, in mild winters, sadly destroys the foliage of brassicaceous plants, and often attacks them while quite young. A third production of this kind, but happily of much rarer occurrence, has recently been discovered travelling, as it were, southward. This is *Cylindrosporium concentricum*, figured nearly thirty years ago by Dr Greville, and at that time abounding in the vicinity of Edinburgh, and detected by several botanists. Its first detection in England was only in 1850, and that no farther south than Northamptonshire. It spreads rapidly over the surface of the upper and under side of the leaves of most of the Brassicæ, the cauliflower in particular. These parasites have been minutely examined by the Rev. M. J. Berkeley, A.M., F.L.S., an acute observer in these matters, and are pronounced by him to have no affinity with the genus *Uredo*, and still less with the parasitic moulds to which mildew properly belongs. These humble means at the disposal of a supreme Being, insignificant as they may appear even when viewed under the power of the best

microscopes, are often a scourge to man. Whole crops of Brassicæ have often been completely destroyed by their united force. The only remedy at present known is caustic lime in fine powder, or clarified lime-water, administered to the plants upon the first appearance of the fungi, and continued vigorously until its disappearance. An interesting account of these parasites will be found in the third volume and also in the sixth volume of the "Journal of the London Horticultural Society," to which the cryptogamic reader is respectfully referred. The *Erysiphe communis* (Link, common mildew) is often found on the leaves, more especially in dry weather, for which an efficient remedy has been discovered in flowers of sulphur, thrown over the plants by one of the newly-invented sulphurators.

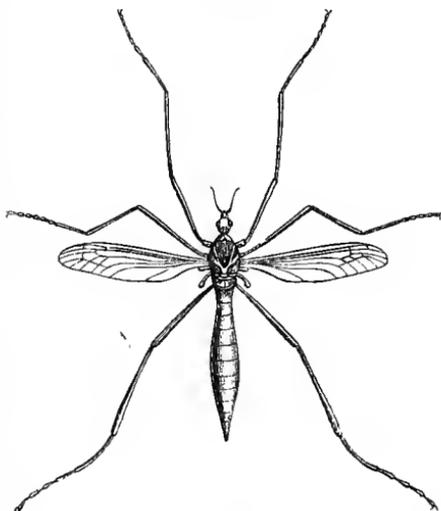

The most fatal disease, however, the Brassica family is liable to, is what is called the club in the root, from the many swellings or tubercles formed upon it, varying in size from half an inch in diameter to two or three. This is the production of the larvæ of *Curculio contractus* of Marsham, which, piercing the skin of the root, deposits its eggs in the hole, lives during a time on the sap of the plant, and then escapes and buries itself for a time in the soil. Frequent transplanting seems to be the first remedy, because by it the plants acquire numerous roots to throw strength into the plant; the next is to draw up every plant affected, and consign it to the flames; the third is next to useless, namely, cutting off the protuberances and retaining the plants. The first has this advantage, that while it greatly encourages lateral roots, the grub preferring those that are ramose, parts of these may be removed, while, at the same time, the others are throwing in support to the plant, enabling it to outgrow the disease. Renewal of soil is important, while the application of the whole list of mineral manures has not had the desired effect. Guano, placed in the holes at planting, has been found beneficial. In new soil this disease seldom appears.—(Vide section TURNIP.)

Snails and slugs are destructive to all the Brassica in a young state; but as a good dusting of caustic lime so completely annihilates them, and a man can go over several acres per day sowing it broadcast, we do not see why we should occupy space with, or impose upon our readers the expense of any other remedy. Slug-picking and snail-hunting has been a stereotyped recommendation since the days of Mascall; it is not in accordance with the intelligence of the present day.

*Tipula oleraceæ*, crane-fly, known in England as gaffer long-legs, and in Scotland as daddy long-legs, is very destructive to most of the Brassicæ in its larva state. The larva is easily known by its long cylindrical body being destitute of feet. The cognomen of long-legs is taken from the insect in its more perfect state. It appears that the best way of capturing it is by setting traps of slices of turnip, potatoes, &c., fixed to a wooden skewer, and sunk a few inches under the surface of the ground. The larvæ will be attracted by them, and if they are pulled up every other day, thousands of them may be found attached

to the baits, and can be readily scraped off and burnt, while the same baits may be reset.

Fig. 40.

CRANE-FLY.

Against the attacks of such multitudes of obscure enemies—and those we have noticed as chiefly feeding upon the cabbage tribe are as nothing compared with the millions of millions that prey upon other productions of his care—all the boasted intelligence of man would not enable him to contend, were it not that nature has so beautifully arranged it that one species of insect is made to feed on another, and thus keep up the balance in regard to their numbers and effects. Birds are great destroyers of insects at all times, but more especially in those stages of their existence when they are most destructive to vegetation; these, therefore, should rather be encouraged than destroyed. All crops can be easily protected from them during the time the seed is coming to maturity, or fruit ripening. Late frosts, hurtful in themselves to vegetation, are equally so to newly-hatched insects; and much of the damage laid to easterly winds and spring frosts may, upon strict inquiry, be found rather to arise from these minute enemies. To this we will have occasion to refer at some length in the fruit-garden department. Inundations during winter do much to thin insects in their subterranean retreats; and this points out to us the utility, where it can be applied, of irrigation, or indeed, laying the ground for a week during winter under water. Some of the most despised mammalia—the mole for example—are insectivorous, and destroy many of our enemies, the larvæ of wireworms being to that animal a savoury meal. So much satisfied are we of their assistance in this respect, that we rather encourage than destroy them. Amongst insects themselves, the genus Carabidæ, or ground beetles, destroy the pupæ of moths and butterflies while buried in the ground. Many of the winged insects actually

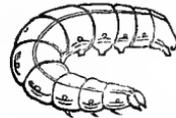

lay their own eggs in the bodies of living caterpillars, and hence cause their destruction. But of all others, the very numerous family of Ichneumonidae are the greatest destroyers, amounting in species to above 1300, the females of all of which deposit their eggs in the bodies of other insects. Ants, not very troublesome in themselves, destroy aphides in vast numbers, and could we induce them to take up their abode in a border of caniflower or early cabbage, the *Aphis brassicae* would sustain a severe persecution.

Catching moths and butterflies is a wholesale mode of lessening the number of forthcoming caterpillars. Searching for chrysalides during winter, and dusting the crops infested with caterpillars, are the most rational means of ridding our kitchen-gardens of such pests; and to those means we may add cutting off the infested leaves, pulling up the roots which they have perforated, and consigning them to the flames, which is of vast importance, and, if persevered in, would almost clear the ground in a season or two. Trapping by placing slices of turnip, carrot, or potato attached to a skewer, and taking them up every other day and destroying the insects attached, is a most effectual method. But these or any other means, if not persevered in, will be as completely useless as all the nostrums recommended either in past or present times. Stimulants such as guano assist in rushing the plants forward, and hence enable them better to withstand the attacks of insects. Spirit of tar mixed with the soil destroys them by insinuating its penetrating poison through their hardest covering; and rape-cake has been found efficacious in a more extraordinary manner, the pupa feeding kinds devouring it until they die of repletion. Any or all of these may be tried with effect in the preservation of brassicaceous crops, but, we repeat, they must be applied in sufficient quantity and persevered in.

The cabbage moth (*Mamestra brassicae*, or *Noctua brassicae* of some entomologists).—During the evenings about the latter part of May, the moth in its perfect state may be seen flying about in the neighbourhood of cabbage-beds, and in July, August, and September, in its caterpillar state, will be found committing sad havoc in the heart of the full-growing cabbages, as well as on the leaves of those less farther advanced. "The moth measures about 1½-inch from tip to tip of the fore-wings, which are dusky brown, clouded with darker shades, and marked with pairs of dark spots on their front edge; from these spots proceed the streaks which mark the wings across; there are various spots on the wings, some yellowish, and those in the middle surrounded with white, the kidney-shaped one with a whitish grey crescent around it, and blackish beyond; the wings have a grey yellowish-striped fringe, and near this, at the point farthest from the body, they have a row of black triangular marks; the hind wings are light-brownish grey, with dark veins; the body and head are of various shades of blackish grey, with a darker stripe of the same colour down the centre of the back. The caterpillar is green, variously marked with grey or black, with a

dark stripe down the back, and a dirty-yellow one down each side. The (spiracles) breathing-holes are white, surrounded with black, and

Fig. 41.

CABBAGE MOTH AND CATERPILLAR.

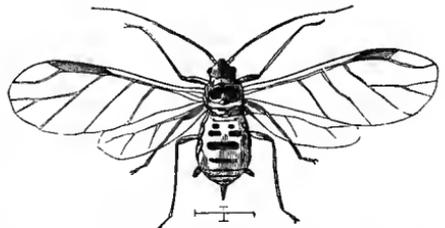

close above the yellow stripe. They bury themselves underground, and remain in the pupa or chrysalis state all winter."—*Cottage Gardener*, vol. ii. p. 83.

Fig. 41 shows the perfect moth and the grub.

The white line brown-eyed moth, *Mamestra* or *Noctua oleracea*, is another enemy of the cabbage tribe. For figure and description, see section TURNIP.

*Aphis brassicae* (common cabbage-louse), fig. 42, the winged male, and 43, wingless female, is

Fig. 42.

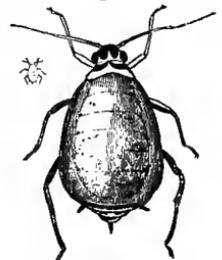

CABBAGE APHIS, WINGED MALE.

injurious in dry seasons. Dusting the plants with black hellebore, Scotch snuff, caustic lime in

powder, are the usual remedies. They usually appear in greatest numbers from the middle of July to the end of November, and are found generally on the under sides of the leaves, the females being surrounded with their young broods, while the males are to be seen wandering about, no doubt in search of mates. The male is pea-green; the head, collar, and back of

Fig. 43.

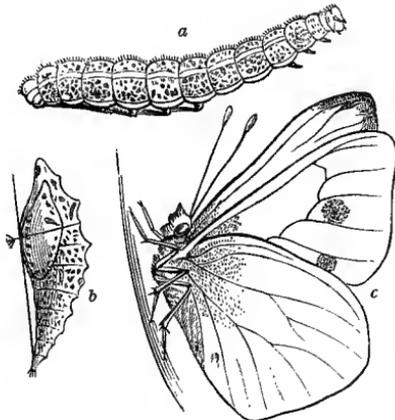

CABBAGE APHIS, WINGLESS FEMALE.

the body black; horns seven-jointed; trunk irregularly spotted with palish black; nervures of wings dark brownish-black; legs black; base of thighs greenish. The female is of a yellowish-green and mealy white, spotted with black; body large and heavy; legs black; base of thighs green; horns shorter than in the male; the two first joints are green, while the third is ochreous; eyes, four in number, two large ones in the head, and two smaller on the collar.

The *Pontia brassicae*.—Well known as the large white garden butterfly, fig. 44, with black tips

to its wings; produces the equally well known green caterpillar, so often found upon the cabbage tribe in all stages of their growth. The caterpillars may readily be destroyed, and by doing so the increase of following years is greatly diminished, by dusting the plants over, twice a-day, as long as the insects appear, with finely-powdered caustic lime, shaken from a thin canvass bag, or by watering them over head with clarified lime-water.

And associated with it are *Pontia napi*, fig. 45, and *Pontia rapa*, fig. 46, the small white-and-

Fig. 45.

green veined garden butterfly. The caterpillar of the first is greenish-yellow, with black spots;

of the second, green, with small yellow rings on the sides of the body; and of the third, green, but striped down the back and sides with orange.

When fully grown, they retire to some sheltered dry place, and change into the chrysalis state, ready again in spring to change into their butterfly state, to lay their eggs, and produce a fresh breed of caterpillars.

The cabbage powder-winged moth (*Aleyrodes proletella* L.—the *Aleyrodes chelidonii* of Latreille) often commits sad havoc amongst the cabbage and broccoli crops in its fly state during the month of November. They begin to make their appearance in May, and live under the leaves where they are hatched, abounding during the months of June, July, and August. They are thus described in "Gardeners' Chronicle" for 1851, p. 837: "The aleyrodes is a minute fly, covered with white powder. The females have been observed about midsummer to remain quite quiet on a leaf for several days when about to lay their eggs; and when they had left the spot where they had rested, a small circular space covered with white powder was observable, around which were irregularly deposited from 9 to 14 eggs. These eggs are transparent, but afterwards turning to a yellowish tint. They hatch in about 12 days, and the young larvæ immediately run a short distance to spread themselves more about the leaf, but in a few hours a scale is formed over them, so that they look like little tortoises or ceccei, and exhibit no signs of life. The colour is almost white, with two yellow spots behind. They are not absolutely stationary, but only move very short distances as they increase in size, being furnished with six pectoral legs. The perfect insect is covered with white powder, the head and thorax black, variegated with yellow; the eyes divided and black; the antennæ nearly as long as the thorax, slender, and five-jointed; first basal joint stout, second very long, third and fourth shorter, the remainder slender; the rostrum bent under the breast in repose; stout, biarticulate, with two very fine bristles passing through; the thorax sub-globose, the collar short, with three black spots; abdomen short, yellow or rosy; the apex obtuse and dark; wings forming a triangle in repose, and more or less deflexed, pure white, mealy; superior wings

largest, with a single nervure curved at the centre, where there is an obscure black fascid, with a black spot at the extremity; inferior wings smaller, with a central longitudinal nervure; six legs, rather long, black, and powdered with white; feet long, and composed of two equal joints, terminated with two very fine curved claws, with a hook between them. These little creatures seem not only to withstand the cold, but even to multiply during the winter; for Reaumur says he found them in every state in December and January, as he had done in summer; and this will account for their extraordinary increase, which, from the small number of eggs laid by each female, appears at first to be inexplicable. Moreover, in less than a month the insects undergo all their changes—from the deposition of the egg to the pairing of the perfect progeny; it is therefore possible to have twelve generations in a year. Reaumur calculated that a single female might, in the course of a year, give origin to 200,000 descendants."

The best mode of lessening their numbers is to gather the infected leaves during winter and spring and burn them. Any choice plant attacked by them might be fumigated with tobacco smoke; and, indeed, small crops might be covered with canvass, and undergo the same operation; but such and all other means hitherto tried would be impossible with crops upon a large scale, as the brassicaceous tribe in general are.

In some seasons they are more destructive than in others, and would become a frightful scourge to man, were it not that they have their natural enemies in a species of Cynips, and one also of Acarus, which feed upon them.

*Anthomyia brassicæ* of Bouche (the cabbage-fly).—The larvæ of this insect live underground, in the roots and stems of most of the Brassica tribe, eating passages through them, and causing them to rot. It is one of the most destructive of insects, and is thus described in "Gardeners' Chronicle," 1841, by the authority above cited: "The male is darker, but of a brighter grey, with black bristles; there is a black stripe half-way down the middle of the thorax, and a curved one on each side; the body has a more decided black stripe down the centre, and the segments are marked by a line of the same colour; legs and antennæ blackish; wings a little smoky. The female is pale ashy grey; the eyes remote, with a dark chestnut-coloured stripe on the crown; the wings are similar

in tint to those of the foregoing species, but the insect is considerably smaller, and this is the only striking difference between the females."

*Ceutorhynchus sulci-collis* of Gyllenhal, fig. 47, the *Curculio pleurostigma* of Marsham, deposits its eggs beneath the outer covering of the stems of cabbages, as may be discovered during winter and

spring by the appearance of numerous galls or small excrescences covering the stems close to the ground. Those are produced by the deposition of the eggs of this insect. On opening these galls, a small white maggot will be found within, without legs, the body being curved and fleshy, the head is palish orange, with chestnut-coloured jaws, the tips of which are black, as are also the two small eyelets, one on each side of the head. These larvæ, when fully grown, quit the galls and secret themselves in the soil, and remain there to undergo their transformation, first to the pupa state, and next to the perfect weevil, being about one-eighth of an inch long, of a black shining colour, slightly covered with greyish hair, the head and pro-thorax coarsely punctured; the cases of the wings have ten lines impressed on each, the interstices rough, the under side of the body covered with scales of a buff colour. The best remedy in the case of young plants is, as soon as the galls appear, to pull them up and burn them, by which means a riddance is made of the brood. To cut off these galls weakens the plants greatly. It is much the safest way to burn the plants at once.

Amongst other insect enemies that attack the cabbage tribe, we have reason to suspect one or

Fig. 48.

SNAKE MILLIPEDE,  
Natural size and magnified.

two species of *Iulus* (snake millipedes), fig. 48, as they are often found in great numbers buried upon the roots in a putrescent state. They may be detected in

spring, in the roots of such cabbages as have suddenly died when about half-grown. When in that state, if the plants are pulled up, the roots will be found in a state of decay just under the surface of the soil, and in the decayed part multitudes of millipedes will be found. The editor of the "Cottage Gardener" queries their being the cause, and remarks, vol. ii. p. 139, "The question arises, Is this insect the cause of the disease by wounding and eating the bark of the plant? or does the parent wound the bark, depositing her eggs in the wound, and when wet, and the irritation produced by the larvæ, complete the fatal wounding? or does the decay first arise, and then this millipede comes to it to feed upon the putrid part, and the mites (*Acari*), which frequent the places where decaying vegetable matter occurs?" This question appears as yet undecided. Mr Johnston's opinion is quite in accordance with our own, namely, that this "*Iulus* does not attack the cabbage whilst this is healthy, but that the wound may be occasioned by the parent millipede, and that the young ones feed on the mites which frequent the decaying wound. The millipede, *Iulus pulchellus*," represented in our figure, "which is oftenest met with in these circumstances, is of a sandy-grey colour, having on each side a row of small crimson spots. The number of legs varies with the age of the insect, but the greatest number observed in *Iulus pulchellus* has

Fig. 47.

CURCULIO PLEUROSTIGMA.

been about 170. When disturbed, it coils itself round in the way represented in fig. 48. It has been found in decayed onions and pansy roots, as well as in cabbage stems. Quick-lime and gas-lime, incorporated with the soil, destroy or drive away these creatures."

The cabbage is also infested by the *Altica consobrina*, or blue cabbage-fly, or flea-beetle, attacking the leaves; *Anthomyia trimaculata*, destroying the roots; *Altica concinna*, the brassy cabbage-flea; *Vanessa fluctuata*, the caterpillars of which feed on cabbage-leaves.

*Saving seed.*—The whole of the Brassicæ are liable to change when grown from seed. They cross with each other so freely that it is scarcely possible to save the seed of any one variety with a certainty that seedlings from it will invariably come the same as the parent. Certain winged insects, such as bees, engaged in sucking the honey-like matter contained in the nectary, an appendage to the flower known to secrete honey, and which is strongly exemplified in many cruciform flowers, to which tribe the Brassicæ belong, carry the pollen or fertilising dust from one flower to another, and thus become the agents of nature in the creation of cross breeds, for hybrids or mules we cannot call them. Nor is it only in the same garden that these causes of intermixture take place; they extend over much greater surfaces—often to the extent of a mile or more; and although we know that such do exist, we do not always know when and where they take place. It is impossible to save several kinds of brassicaceous seeds pure in the same garden, although Knight and others attempted this by covering over the flowers with fine gauze netting, and even by castrating the flowers when artificial impregnations of opposite plants were in course of experiment. It is, therefore, folly in people to save their own seed, unless their garden is far isolated from all others, as well as from fields where brassicaceous plants are cultivated. It would be, in a sense, foreign to our present purpose to follow this very interesting question further; we will direct our attention now to the best means of saving seed, presuming only one sort is saved in the same garden within the same year.

*Cabbage-seed.*—Select some of the best-formed specimens of the sort to be saved. They may either remain in the place where they have been growing, provided the climate is good, or the roots may be taken up and planted in the best situation the garden affords. In very cold and wet localities they should be planted at the bottom of a south wall, and when replanted should be set so deep in the ground that only a few inches of the stem may appear above ground. In spring they shoot up, and during summer the flower-stem is formed, and the flowers produced. The side branches of the stem should be cut away, as it has been proved by Bastien that the middle flower-stem produces the best seeds, and that plants produced from them are much earlier, and more perfect in character, than are those produced from the side or lateral branches of the flower-stem. No doubt it would be of use as a precaution to cover the

flower-stem, as soon as the flowers began to open, with fine gauze netting, were it only to protect them from the operations of the bees and other winged insects. Flower-stems from the sprouts should not be allowed to exist. In a few days after the flowers begin to open, impregnation takes place; after that the covering may be removed, for no spurious impregnation can take place afterwards. Great care should be taken that the flower-stems are supported so as to prevent their being broken by wind or otherwise, and also that the seed is allowed to ripen thoroughly. To secure such, it will be necessary, as soon as the seed pods are formed, to cover them with netting, so as to exclude birds from them, and also that the stalks should be cut before the pods begin to open and shed their seed. All this may be considered trouble, but without such precautions no dependence can be placed on the purity of the stock. Common seed-growers do not bestow this attention, because, at the miserably low price at which all kinds of seeds are now sold, it would not remunerate them. They do their best, at least such of them as have a character to maintain. They visit their stock-farms frequently, and weed out all inferior plants, and do their best to secure a fair sample. They also avoid growing plants of the same natural order near to each other, unless it be such as do not flower at exactly the same time. The critical period may, in a general way, be embraced within the space of a week, and there are several of the Brassicæ that do not perfect their flowers within that period, and hence such may be grown side by side. Such, however, as experience has taught the seed-growers flower at the same time are grown on separate farms, or else they confine themselves to a less extended number of sorts, and occupy the ground with pease, beans, carrots, &c., from which there is no fear of contamination. Some, upon a small scale, plant their varieties of Brassicæ on spots in the centre of corn or other grain fields, and this greatly lessens the chances of intermixture. Seed-saving in private gardens is by no means a profitable speculation; yet from the frequent disappointments we meet with, we are often driven to it as a measure of necessity. A superior stock of Brussel sprouts, or of Walcheren broccoli, or of a favourite cabbage, is of too much importance to lose wantonly. Here, however, there is the consolation that as the seeds of most of the Brassicæ will keep good for six or eight years, and even longer, we can save Brussels sprouts one year, Walcheren broccoli the next, and so on, including those other sorts that do not flower at the same time. The seed, when ripened, keeps best in the straw (using the phraseology of the trade), and where there is accommodation this may be done; otherwise, the seed may be thrashed out when ripe, and kept in paper or canvass bags in a dry airy seed-room. It is of advantage to the seed, and a precaution against weevils, to examine the seed three or four times during the year, and to turn it out into a seed-sieve which has been already rubbed over with salad oil, and to toss the seed about in it until the skin receive a slight coating of the oily matter, which will pre-

vent the weevils from attacking it, and, by excluding the air, tend to prolong the vegetative properties of the seed. All the Brassicæ seed is better of being kept for a time, for reasons elsewhere given.

*Brussels sprouts*.—It is usual to save the seed indiscriminately from the flowers which proceed from the crown of the plant, as well as those which issue from the side sprouts. In both there is a difference. The experiments, in this respect, which we have been engaged in for some time, are not yet sufficiently matured to warrant us in offering an opinion, which may some day be considered rather novel. Dr Van Mons of Brussels held the opinion that seed saved from the crowns or tops was preferable to such as originated from the side sprouts.

*Cauliflower and broccoli*.—Both require a warm sheltered situation, yet one fully exposed to the sun—the former in particular; and hence its seed is seldom well ripened in Scotland; indeed, our best seed comes from Holland. The very finest and most perfectly formed heads should be selected, carefully taken up, and replanted. In spring, when the broccoli flowers begin to expand, the centre part should be cut out, leaving only five or six of the outside flower-shoots to come to seed. Transplanting the old stems from where they grew to where they are to produce their seed, is thought greatly to improve its quality. By the check the plant gets during the operation, it is so far weakened that it is not so apt to button, or even prematurely to flower; nor so likely otherwise to degenerate as it would be, if continued in its original place. The best remedy for either is seed well kept for several years. It was long thought that these seeds should be imported annually from Italy; but this, so far as the broccoli is concerned, is quite uncalled for, as we have finer varieties of English origin than are to be found in Italy or anywhere else. The only difference in saving cauliflower seed is, that the plants require a warmer situation to be placed in, and instead of planting the stems in spring, as with broccoli, the plants of the last August sowing, preserved during winter, should be chosen: and as they produce their flowers or heads during May and

June, the best specimens should be selected, and left where they are growing, that they may experience no check to delay the season of ripening their seed. The same precaution should be employed as noticed for cabbage, and every encouragement given to accelerate their period of ripening. Our best cauliflower seed is imported from Holland, and for its quality we have much greater reason to thank the better climate than the growers, who are not over particular in the matter, as Dutch cauliflower seed is sure to sell.

The European names of the common *white cabbage* are—Chou pomme, or Cabus blanc in French; Cavolo in Italian; Verca in Portuguese; Wiss kopf kohl in German; Berza in Spanish; and Witte kool in Dutch. The Portugal cabbage, or Couve tranchuda, is the Chou vert à larges côtés of the French.

*Red cabbage*—Rood kool in Dutch; Berza colorada in Spanish; Chou pomme-rouge in French; Cavolo rosso in Italian; Roth kopfkohl in German.

*Savoy*—Herzkohl, or Wirsing, in German; Cappucio in Italian; Chou de Milan, ou Pomme frise in French; Savooij kool in Dutch; Berza de saboya in Spanish.

*Brussels sprouts*—Chou de Bruxelles, or àjets, in French; Sprossen kohl in German; Spruit kool in Dutch: so little cultivated in the south of Europe as to have no other name than the French, Chou de Bruxelles.

*Borecole*—Chou verte, or non pomme, in French; Cavolo aperto in Italian; Col in Spanish; Grune kohl in German; Groen kool, Dutch; Kale, Saxon; Open kale, Scotch. The palm borecole is the Chou palmier, and turnip-cabbage Chou navet of the French.

*Cauliflower*—Chou-fleur in French; Bloem kool in Dutch; Berza florida in Spanish; Blumen kohl in German; Cavoli fiori in Italian.

*Broccoli*—Broccoli in French; Broccoli in Italian; Brocoli in Spanish; Scotsche kool in Dutch; Italianische kohl in German.

*Sea-kale*—Chou marin in French; Col marina in Spanish; Meerkohl in German; Zeekool in Dutch; Crambe marina in Italian.

## CHAPTER IV.

### ASPARAGINOUS PLANTS.

THIS division comprises five sections of esculents, cultivated more as articles of luxury than of general utility; they nevertheless form a most important division in garden arrangement, often occupying an eighth part of the whole extent.

#### § 1.—ASPARAGUS.

*Natural history.*—Asparagus (*Asparagus officinalis* L.) belongs to the natural order Asphodelæ, and to the class Hexandria, and order Monogynia, in the Linnæan arrangement. The name is derived from (*A. intens*) *sparasso*, to tear, on account of the strong prickles with which some of the species are armed. It is by no means a genus having much floral attraction, most of the species being rude climbers, with insignificant flowers; in general natives of warm countries, and of little value either in the arts or in domestic economy. One is a native of Siberia; and the common cultivated sort is a native of light sandy soils on some parts of our sea-shores, as well as of the salt-water steppes of Russia—where it becomes covered with sand and salt water during high tides—and other parts of the north of Europe.

It is said to attain an extraordinary size in a wild state on the banks of the Euphrates, and it has been suggested that roots of it should be imported to this country; we believe, however, that it owes its great size there to local circumstances, and that roots from these would with us become no larger than our own. The first notice taken of it as a cultivated plant is about 200 years B.C., in the time of Cato the elder, who lays down very sensible rules for its cultivation—much, in fact, as at present practised—and very wisely recommends that the beds should only be allowed to remain in a bearing state for nine years. Suetonius, in his Life of Augustus, informs us how partial that emperor was to asparagus; and Erasmus confirms this. Pliny, in book xix. chap. 4, tells us that it was cultivated in the gardens at Ravenna in his time, of an enormous size, so that three heads would weigh a pound. Mr Grayson, of Mortlake, near London, has produced 100

heads that weighed 42 lb., perhaps the largest ever grown in Britain. Gerard is the first English author who notices it, and calls it *sperage*, a name, within our own recollection, used by some old gardeners. He derives the name asparagus from the Latin *asparagi*, which he translates to signify “the first sprig or sprout of every plant, especially when it be tender.” Gerard wrote in 1597. It is most extensively cultivated around London, many hundred acres being occupied with it—some individuals, such as Mr Grayson, having from 30 to 40 acres under this crop alone. Around Paris and Vienna it is extensively grown, and that to great perfection. Meager, in his “English Gardener,” p. 188, informs us that in his time (1670) the London market was well supplied with forced asparagus; and the means employed then were much the same as those at present in use, namely, placing the roots on warm dung-beds.

*Uses.*—Its delicate flavour is rather deteriorated than improved by those additions which a skilful *chef de cuisine* deems necessary in the preparation of most other vegetables. It is usually boiled and served alone, to be eaten with melted butter and salt. It is also served on toasted bread, with a plain white sauce. The small heads are cut into pieces of  $\frac{3}{4}$  of an inch each, and served plain boiled as a substitute for green pease. In this latter way much of what is called the *sprue*, or small heads—or *grass*, as all asparagus is called—which reaches Covent-Garden Market is disposed of. Medically it is considered diuretic, and in Paris is much used by people of sedentary occupations, like tailors, weavers, authors, &c., when they are troubled with symptoms of stone or gravel. It is said to promote appetite, and hence is served at an early period of the dinner. It is considered anti-scorbutic, and very good in dropsical cases, but is to be avoided by those troubled with gout. The roots possess those healing properties more than the sprouts or buds; and, if we are to believe Galen, Hoffman, Dr James, &c., it is because the roots contain more of the salt, from whence they derive that quality, than any of the parts grown above ground, which cannot imbibe it so copiously as the root itself receives it from the ground. It operates with much effect on the urinary organs, as all who eat it copiously know full well. But the most extra-

ordinary virtue attributed to this plant is given by Antoine Mizold, "Cent. 7, Memorab. Aph.," 34, and Schenck, "Obs. Med. L.," i.—"If the root is put upon a tooth that aches violently, it causes it to come out without pain." Modern dentists do not believe in this—nor do we. In Queen Elizabeth's time, asparagus was eaten "sodden in flesh-broth, or boiled in fair water, and seasoned with oil, vinegar, salt, and pepper, then served at table as a salad." It makes excellent soup, and is also used when ragoued. The part used is 3 or 4 inches of the young shoots or buds, taken just as they appear above the ground, which is generally in May and June. It is most esteemed when of a nice fresh green colour. The French blanch it, but they destroy the flavour peculiar to it by such means.

*Propagation.*—In the first instance, all asparagus is originated by seed. It is then replanted when of one or two years' growth: the first, if the roots are strong, is preferable.

*Sowing and planting.*—March is the best season for sowing. Some recommend sowing broadcast in beds; we have a *penchant* for the drill system, and in this case would recommend it. Prepare the ground by copious manuring, and deep-digging or trenching. Draw the drills a foot apart, and 2 inches deep. Sow thin: the seed is in general good, so there need be small allowance made on that account. One quart of seed will be quite sufficient to sow a bed in the broadcast manner of from 36 to 40 square feet. If sown to remain on the same ground (a practice seldom thought of in first-rate gardens), then a pint of seed will sow a bed  $4\frac{1}{2}$  feet broad by 30 feet in length. If the plantation is to be formed of roots from last spring's sowing, then 160 plants will be required for a bed  $4\frac{1}{2}$  feet wide and 10 yards in length. This is the age at which they should be planted. The above calculation is made presuming that the usual practice is followed of setting four rows in a  $4\frac{1}{2}$ -foot bed, and the roots 9 inches apart. We would rather plant three rows in such beds, and give the plants 12 inches from plant to plant, which will reduce the number of roots required, and tend greatly to the future welfare of the crop. Plants of one year's growth we prefer; but much depends on the way they have been grown, for sometimes one-year-old plants are stronger and better than three-year-old ones, where little attention has been paid to them. In this case, as in most others, plants sustaining a check in their

early growth from starvation are seldom so luxuriant or so long-lived as those which have been carefully nursed. In sowing for permanent crops, it is best to sow in  $4\frac{1}{2}$ -foot beds (three rows say, 18 inches apart), and when they have advanced to the height of 6 or 7 inches, to thin them out to 12 inches in the line; or, as we have often practised, sow in single rows 3 feet apart all over the piece, and thin out the plants to a foot apart in the line. It is usual—and we find no fault with the practice—to sow a crop of onions along with the seed the first year: the onions, being sown broadcast, will not much injure the asparagus, while they will repay for the culture of the whole. For permanent crops we prefer the single-drill system; but for growing for two, three, or four years, for the purpose of taking up the roots for forcing, it is possible that the  $4\frac{1}{2}$ -foot bed, with three rows in each, may be preferable. This is certainly the case in petty gardens, where a bed of the above breadth, and 10 yards in length, may be the extent to which the owner's means permit him to extend. This is, however, scarcely a crop for *manse gardens*; the small return only sets the mouth watering, and may lead to a breach of what is forbidden by the tenth commandment.

Whether the seed is sown broadcast or in drills, with a view to be transplanted afterwards, it will be requisite the spring following sowing to prepare the ground and beds for transplantation; and in this it matters little whether the roots are to be set in single lines, or two or three rows, in beds of the above breadth. The whole ground should be prepared alike, and the plants carefully removed to it.

In preparing the ground, we need hardly say it cannot be too highly enriched or too deeply trenched, the roots often extending 3 feet under the surface. It should be trenched to that depth, and a supply of manure placed in the bottom of each trench after it has been broken up with a pick—a foot more in depth, if the soil admits of it. As the process of trenching goes on, other layers of manures should be laid on each respectively, as it is from a foot to 3 feet in depth that the roots will be in search of food. The more lasting and permanent the manure applied the better, so that its decomposition may go on slowly as the roots require it. Some, and

with great advantage, retrench the ground again in an opposite direction, to insure a more thorough amalgamation of the soil and manure together. The operation should be, if possible, carried on during winter, but not when the ground is either wet, frozen, or covered with snow, having it ready for planting in March or April for Scotland. The London market-garden practice is as follows:—"The beds are prepared by putting on an immense quantity of manure, and trenching the ground 3 or 4 feet deep, mixing the manure as the work proceeds. In March the ground is measured out after the following manner: Suppose a fence runs north and south, or otherwise, 3 feet is allowed between it and the first row; a drill is drawn about 2 inches deep, and the seed is sown thinly, say 6 inches or a foot apart, which gives choice of drawing out the weakest, in order that the permanent crop may stand 1 foot apart. The next row is sown 18 inches from the one just mentioned; then for the alley and two sides of the bed 5 feet are allowed; then another row of seeds, and so on, which gives two rows to each bed. The first year, onions are generally sown all over the ground; the second season, lettuce, or any dwarf-growing vegetable that will not choke the asparagus; and so on, until the third year, when the beds are formed out, and a few inches of mould dug out of the alleys, and put on the crowns. Only a few, however, of the finest heads are cut this year."—CUTHILL in *Market-Gardening round London*, p. 18. We adopt another plan:—The ground is first thoroughly enriched, by laying with the stableyard manure a considerable portion of ground bones, say 2 inches in thickness, not very small, and about half an inch in thickness of rock-salt in the bottoms of the trenches, adding alternate layers of dung, with which salt is incorporated, and soil as the trench nears the top; and when the whole piece is thus trenched, we proceed to plant in the following manner: For single lines, trenches are taken out 1 foot in depth and 3 feet apart; in these the roots are placed, having been carefully taken from the seed-bed, with their most minute rootlets preserved, and carried to the spot in a shallow basket or planting-tray, and covered over with a little soil—for few plants suffer more than

this by having their roots exposed to the air. The plants are examined to see that their buds are perfect, and are placed in the trench 14 inches apart, and the roots carefully spread out and covered with the soil, keeping the crowns about half an inch under the finished surface of the bed. When the bed system is followed, the ground is measured off in breadths of 5 feet and 2½ feet alternately: the former are the beds, the latter the alleys. Beginning at one end of a bed, a trench is taken out *across* the bed, 12 inches deep, or more if the roots exceed that length, for they should be laid in at their full length. One root is placed in the centre of the trench, and one on each side of it, 15 inches from each other. When these are planted, another trench is taken out, of the same dimensions, and 18 inches from the first, and planted in like manner. If the ground is dry, the whole gets a good watering of liquid manure—either diluted cow-urine, or water in which guano has been dissolved at the rate of 6 lb. to 50 gallons. The beds are left uncropped, and kept clear of weeds during their growth. Some have planted successfully in May, and even in June, after the plants have attained a considerable size. We mention this, more that advantage may be taken of it to make up any deficiencies that may arise from any of the plants having failed, than with a view of recommending it as a general principle. The seeds require about three weeks to germinate. The smallest asparagus bed that should be made should contain a rod (272 square feet, a little more than 30 square yards) of ground, as upon less than this a dish could scarcely be at any one time gathered. The extent of ground for an ordinary private family should not be less than 5 poles, which should yield about 125 heads daily for four weeks; but for large gardens, from one-eighth to a quarter of an acre will be required, exclusive of that which may be taken up yearly for forcing, which in many cases will require as much more.

In preparing ground for this crop, we have remarked that it cannot be too highly enriched, and that the manurial application should be kept near the bottom. This is because the crop may have to remain on the same ground for from seven to ten years, and therefore it

would be difficult to apply manure to it afterwards ; besides, it is at the bottom of the soil that the spongiolets of the roots are chiefly placed, few being near to the surface. And although the asparagus is a native of poor drifting sand, still, as its chief merits rest on the size and tenderness of its shoots, it follows that, to insure this condition, they should be stimulated to the greatest extent possible, both by manure, and by being placed in the warmest part the garden affords. In sowing for the formation of a permanent plantation, some excellent cultivators sow in rows 2 feet apart in April, thinning out the plants to the distance of 1 foot from each other. Every alternate row is taken up the second year for forcing, thus leaving those that are to form the crop at the distance of 4 feet row from row, cropping the ground between them with summer cauliflower, which enjoys a partial shade from the asparagus. They also recommend, if the transplanting system is to be followed, that the operation be performed in April, when the young shoots are 3 or 4 inches long. The crowns are kept near the surface at planting ; and in October, 2 or 3 inches of rich manure is laid over them, and is slightly forked in amongst the roots in the spring following ; but no soil is ever laid over them, and all the future care is an annual top-dressing as above, with liberal supplies of liquid manure, in which salt is mixed at the rate of 2 ounces to a gallon.

The Vienna mode of planting asparagus is to trench the ground 5 feet in depth, and to place a layer of bone, horn, chips of wood, or branches of trees, a foot in thickness, at the bottom of each trench ; while the French practice is to excavate a trench 5 feet wide, and of the length the bed is intended to be. The best of the soil removed is reserved to be mixed in the following manner, viz. :—6 inches of best dunghill manure is laid along the bottom ; over that, 8 inches of turf, 6 inches of dung, 6 inches of the best of the soil that had been removed and well sifted, 8 inches of turf, 6 inches of very rotten dung, and then 8 inches of the good earth removed at the excavation. The last two layers are then to be well incorporated together, and the beds formed 5 feet in breadth, with alleys 2 feet broad between them. The roots are then

planted 18 inches asunder, placing a handful or two of mould under the centre of each, so that the roots may be spread out in regular order, and in form of an expanded umbrella, their crowns being kept  $1\frac{1}{2}$  inches under the surface. A small peg is then placed at each plant, and a spadeful of fine sand is placed over the crown, which finishes the operation. The plants should not be transplanted too early in spring, as there might be a possibility of some of the roots being overlooked, which might be deficient in healthy buds. To guard against that, defer planting until they have sprung an inch or two inches in length. Some defer it longer, and thus reason : Early in spring is the period in general recommended for making new plantations of this plant. Custom only sanctions the practice, while experience says custom is in this case a fallacy, and recommends the operation to be performed late in May, or even early in June, and that when the plants have attained the height of 10 or 12 inches.

In cold situations, this late planting is of the utmost consequence, and if attended to, would in a great degree remedy the defects, so often seen, of blanks in the beds, and not unfrequently the dwindling appearance of the whole crop during the first year. Many will no doubt object to this late spring planting, from a dread that the plants will suffer from removal while in a state of growth ; and others will argue that, by following the "good old rule" of planting in March, the plants will have a longer season to grow in, and also that the roots will sustain less injury, because they have not then become excited into growth. All these fears are groundless : the young shoots, should they even perish, will be succeeded by much stronger ones from the latent buds, with which the crown of the plant is always furnished ; and others may be consoled by the fact, that, the ground being much warmer in May or June than in March, and the juices of the plant being in motion at the time, it is prepared to encourage immediate growth ; whereas the roots transplanted in March lie, till excited by the natural warmth of the soil, in a dormant state—the elaborated sap in them escaping at the injured parts, weakens them amazingly, as well as brings on a disposition to rot and decay. Keeping

the beds well elevated, in cold soils and situations, enables the solar rays to reach the roots better than when planted on a level surface.

*Subsequent cultivation.*—We need hardly say that the beds should be kept free of weeds, as well as the alleys between them. The plants on seed-sown beds should be allowed three years to establish themselves, before any buds are gathered. Those on transplanted beds, if the roots were strong at planting, and have made good progress since, may have a few of the strongest buds gathered the second year; the third, if all has gone on well, will admit of regular cutting. The practice of cropping the transplanted beds is injudicious, and that of cropping the alleys between the beds, although constantly done, is of questionable utility, because whatever crop is planted has a tendency to rob the beds; and the roots, which often extend towards them, run great risk of being either cut off or very materially injured. Mr Judd, in the "Transactions of the London Horticultural Society," vol. ii., thus very properly speaks on this point. Having dug out the alleys the first season, instead of repeating the operation the next, he lays on a coating of rich dung 3 inches thick, and carefully forks it into the beds and alleys—a process he continues in winter annually, "never digging out the alleys any more, as it is known the asparagus plant forms a fresh crown every season; and sometimes it happens that in a few years the crown will increase almost into the alley, so that in digging out this you must inevitably spoil that plant. If this is not the case when the beds are in a good condition, the roots will be sure to work out at the sides into the alleys; and by digging out the latter, these roots must be cut off, as you will often see them exposed all the winter, before dung can be got to fill the alleys up. Rather than be treated in this way, they had better be without anything all the winter, as asparagus does not suffer generally by frost." The practice of covering the beds in autumn with leaves or litter is sufficiently absurd, yet top-dressing them with rich manure is of great advantage; but this dressing, whatever it may be, should be covered with a couple of inches at least of soil, to prevent the escape of its gaseous

matter into the air. The rains of winter will wash down to the roots much of its fertilising properties; and in spring, part of it may be carefully raked off, and left to rot in the alleys. That which remains on the beds will prevent the crowns from rising above the surface, and tend to exclude the drought. It has been recommended to uncover the crowns during winter, and to cover them over again in spring—a very useless, if not an injudicious practice. The surface of the beds should be slightly stirred up with a fork in spring, and before the buds show above ground; and three times during the growing season of the plants, a thin sprinkling of salt should be applied to the surface, and, if possible, before rain. Upon the whole, disturbing the ground in the alleys, further than loosening it to the depth of 4 or 5 inches with a three-pronged fork every spring, is reprehensible; and still more so, digging them out in deep trenches, and piling the soil over the beds, as practised by many of the London market-gardeners, who do so to obtain stalks, or *grass*, as they term it, nearly a yard in length—all of which, excepting about 3 inches at the top, is perfectly useless, and well defined "drumsticks" in "The Gardeners' Chronicle"—an immense expenditure of the energies of the plant, for no other purpose, that we could ever divine, than to encumber the dust-holes in London. The practice is still persisted in, notwithstanding the merited castigation the advocates of such an absurd practice received a year or two ago from Mr Cuthill and the editor of that journal.

Top-dressings, however, can be of far less advantage to the plants than laying a good foundation for them at the first making of the beds, because the spongiolets, or food-absorbing parts of the roots, are in all cases at their very extremities, however deep they may be; and hence it would be excellent, had we the means of applying food to them by means of a sort of subterranean system of irrigation, so that the food might be presented to those parts of the roots which are designed expressly for its absorption. No doubt, much of the success of the noted asparagus grown along the banks of the Thames is owing to the food conveyed to the roots by the rise of the tide, supplying it at a

depth of 3 or 4 feet at every flow—a depth that scarcely any manurial application, applied to the surface, could reach, or at least to the extent of being very beneficial.

The London market-garden practice is thus described by Mr Cuthill: “Autumn arrives, and when the haulm is cut, the whole of the ground is forked over, and planted with cabbages, ‘cole-worts, or winter greens; then in spring the beds are largely supplied with mould out of the alleys, covering the crowns from 8 to 10 inches deep. The finishing of the cutting must be left to the grower. A fair crop of heads must be left, after four or five weeks’ cutting, in order to grow the buds for the next year’s growth, and to restore to the roots what has been taken from them in the shape of a crop; but not one head must be allowed to grow until you leave off cutting entirely, at the end of the fourth year. When the haulm gets ripe, it is to be cut down, and the mould thrown into the alleys, and there enriched; and the whole of the beds and alleys are planted again with cabbages, greens, &c.”

The exact season for cutting down the haulm must ever be governed by circumstances. In early soils and situations, the haulm will be ripe about the middle of October, and this is known by its becoming of a yellowish colour, and by other evident signs that vegetation has ceased for the season, at which time it may be safely cut down. In Scotland generally, in consequence of our late springs, and consequent late autumns, the plants drag out a weary existence to the middle of November, unless some early autumnal frost intervenes to put a stop to growth, which of itself is tantamount to cutting too early, because in both cases the supply of elaborated sap is cut off from the roots. Cut the haulm off in a dry day, and tie it up in bundles, to be kept dry till spring, when it will be found one of the best protections to dwarf standard and other fruit-trees, for which see FRUIT-GARDEN.

In Holland, all the asparagus is blanched, which is effected by covering the beds early in spring with fine sand, which no doubt produces the shoots of a milky whiteness, and of a considerable size and tenderness, but totally devoid of its natural flavour. Not a single bud is to

be seen above ground, the surface of which is kept as smooth as possible; and the state of the crop is ascertained by the buds pushing up little hillocks of the fine sand, when the owner, constantly on the watch, slips down his knife, and cuts off the shoot near its bottom, being guided as to its position by the upheaving of the sand. In defence of their practice, the Dutch say they have the whole shoot in a state fit for the table, while we have only a couple of inches.

Asparagus roots may be removed, with very good success, if carefully done, even at the age of eight or ten years, but it would be unadvisable to cut any of the buds during the following year.

*Soil and Manure.*—The asparagus is a native of sandy beaches often overflowed by the sea, having its roots watered by the spring-tides, yet not kept in a state of continual wetness, on account of the ready means the water has of escaping by filtration. This seems to point out certain principles in its cultivation—namely, a deep, pervious, light soil, perfectly dry at bottom, but capable of being subterraneously irrigated at times—the depth and lightness of the soil being favourable for the long delicate roots penetrating it in search of food. Such are the natural conditions of its growth. The artificial ones should in some degree assimilate to them, with the addition of abundance of manure to increase its size and expedite its growth; for on its large size and rapidity of growth much of its delicacy and flavour depend. A deep light soil can in many cases be formed for it, and subterranean irrigation would even be a more simple affair. On these conditions much of the extraordinary success of the growers along the banks of the Thames depends; and were there even doubts of that, other evidence could be adduced—as that of the well-known fact that the finest asparagus grown in France is produced in a small sandy island in the Oise, where the surface of the beds is not more than 2 feet above the level of the river, the soil being a coarse gravelly sand, saturated with water at the depth of 3 feet from the surface. The banks of the Danube and Euphrates, as we have already stated, are celebrated for the size and quality of their asparagus. Many years ago we saw, for several consecutive seasons, very fine crops

produced by Mr Foster, a market-gardener at Winchester, whose ground was liable to be overflowed by the river Itchen through the winter and spring; and so much did this affect the crop, that he used to cut heads of good size four weeks before it was produced in the neighbourhood of London, and five weeks earlier than we cut at Stratton Park, at a distance of only eight miles. The soil should not be less than 3 feet in depth; and where it is not naturally so, it were better to elevate the beds to that extent by adding to their surface, even by leaving the alleys wider, and taking a portion of the soil out of them for the purpose. A deep alluvial soil is excellent; a strong retentive clayey one the worst possible, and quite unsuitable if not rendered dry at bottom. As to manures, whatever they may be, salt should be incorporated with them, and they should be of the most lasting description, such as ground bones; and the proper mode of employing them so as to be of the most advantage, is by placing them as deep as the roots will penetrate; and as refreshers, copious applications of the strongest manures, in a liquid form, should be applied during the whole growing season.

When salt is applied as a top-dressing during the growing season, it may be laid on until the ground is perceptibly white with it; or if by rule, apply 16 lb. to 60 square yards of surface, which will be quite sufficient for one dressing.

*Forcing.*—By means of slight excitement, this excellent vegetable may be kept in successional fitness for the table from the middle of November until it comes in in the open ground. The conditions necessary to secure success are, strong healthy roots, from three years growth and upwards—carefully preserving the roots on taking them up—and a temperature not exceeding 50° to 60°, with abundance of light and air, after the buds appear above ground. The means employed to effect these conditions are various. First, as to roots: these must be strong and healthy, and hence the supply ought to be grown in the same garden; and to secure them strong, they must be grown in highly-enriched soil. Some cultivators keep up a succession of roots by growing them for the express purpose, and in this case the buds are

never cut, the plants being allowed to develop themselves fully for two, three, or more years, by which means the roots and buds become earlier ripened in autumn, and also have stored up a much greater amount of properly elaborated matter within themselves, upon which depends so much of the succeeding crop. Plants taken out of the ground in October or November, and placed in a state even of very moderate excitement, have not time to furnish themselves with fresh fibres, whereby to supply the roots with a sufficiency of food. The crop, therefore, depends on the amount of properly elaborated organisable matter provided for them during the previous season. This is the reason why a rich-manured soil is dispensed with, and a light sandy one preferred, in which to imbed the roots during the process of forcing, and also why the roots are afterwards thrown away. From this it follows that the greatest possible care should be taken to preserve every portion of the roots at lifting, as each, however small it may be, contains a certain amount of the material so essential in the development of the buds; and as they are prized according to their size, every curtailment of the roots is a certain loss to the crop.

By far the most usual mode of forcing asparagus is to place the roots on a moderate heat, either produced by fermenting material, such as dung, leaves, tan, &c., or on beds heated by hot-water pipes, steam, smoke-flues, tanks, &c. Of these the latter is decidedly the best mode, as affording a steady yet sufficient heat, combined with a greater share of humidity at the roots, as steam will find its way more readily through the joints of a stone or slate-covered tank, than through the closer joints of a hot-water or steam apparatus. It is true, any quantity of water can be supplied to the roots in the other cases, as described p. 447, vol. i., in the case of the roots of cucumbers; still there is something so genial in the heat of a tank, when the roots are in proximity to it, that it seems to approach nearer to that of heat produced by fermenting material than any other.

Whichever of these ways may be adopted for securing heat, the surface on which the roots are to be placed should be prepared of light sandy soil, and on

this the roots, as they are taken up, should be placed close together, and regularly spread out in a perpendicular direction, but not so crowded as that they shall touch each other; and as the process goes on, the soil should be carefully wrought in amongst them while dry; and when the bed is finished, it should be well watered with tepid water, to wash the soil more closely about them.

When the roots are old and very large, it may be found more expedient to place them in a horizontal direction; but, when young, there will be no difficulty in setting them upright, by which a greater number of crowns will be got into the same space. In regard to produce, it may be stated in a general way, that a three-light frame, or the same extent of pit, will produce, under good management, a dish of heads every other day for nearly three weeks. To maintain such a supply from the middle of November till the grass is fit to cut in the open ground, it will be requisite that a three-light frame or pit be planted every ten or twelve days from the last week in October till the second week in April, calculating for the climate of Scotland, and till the beginning of March for that of England. In large establishments, where this vegetable is required daily and in large quantities, double that extent at least should be planted. All that is required in the way of culture is frequent supplies of tepid water and abundance of light and ventilation, even to the extent of removing the glasses for an hour or two on all favourable occasions, and guarding against an excess of bottom-heat. On the Continent, the buds are often blanched with a view to render them more delicate; with us, a fine healthy green colour is a chief recommendation, and to secure this, as well as flavour, light and air are absolutely necessary. As a general rule as to temperature, the atmosphere of the bed or pit should range from  $50^{\circ}$  to  $60^{\circ}$ , the former during night and the latter during the day, while the bottom-heat should approximate nearly, nor should it at any time fall below  $48^{\circ}$ . In severe weather it will be more expedient to retain the heat within by external coverings (for which *vide* fig. 789, vol. i.), than to increase it by an extra consumption of fuel.

*The Dutch and German mode of forcing asparagus.*—About the end of October deep trenches are dug between the beds in the open ground, which, for this purpose, seldom exceed  $2\frac{1}{2}$  feet in breadth, having one row of plants in the centre of each. These trenches are filled with leaves, rank stable-manure, or any other fermenting material capable of producing a strong heat. The surface of the beds is forked up and slightly covered with litter. The heat in the trenches stimulates the roots, and considerable success attends the operation, so far as quantity of heads goes, but they are without either colour or flavour. Some, however, have narrow frames covered with glass which they place over the beds, which is, no doubt, an improvement on the former practice. Both are modes attended with much labour and uncertainty as to time, and occasion an enormous waste of manure. Many Continental gardeners, however, adopt the taking-up system described above, and some also follow the methods to be noticed below.

*Forcing in permanent beds.*—“Forcing in permanent beds has not been much practised in this country till of late years. There are now, however, many instances of this mode,” under different modifications, “in many of our first-rate gardens. Beds to be so treated are built with pigeon-hole walls all round; they are of the breadth of an ordinary-sized garden frame, and of any required length; the depth of the linings or spaces between the beds is 3 feet, and their breadth  $2\frac{1}{2}$  feet. In these spaces dung, leaves, tan, or any other fermentable matter is placed, which heats moderately the body of the beds. Frames are placed over the beds, covered with glass-lights;” all other coverings now should be looked upon as obsolete things. In such beds asparagus is forced year after year without renewal. “For later crops there is no objection to this plan, because, by the time the crop is gathered, the weather will be mild enough to allow the last set of stalks shooting up to their full size and development, and hence the roots will be supplied with proper nourishment to enable them to produce a crop of shoots the following season. But such roots as are forced early by this method, not having the same opportunity of acquiring their natu-

ral supply of food, must reasonably be considered as placed in a very different position as regards their capability of production."—*Practical Gardener*.

*Forcing in permanent pits, as practised in the Royal Gardens at Frogmore.*—The plants while young are planted in brick pits 4 feet in depth, and in a rich loamy soil peculiar to the locality, and highly enriched with rotten stable-yard manure. These pits are 7 feet in breadth, and separated by trenches walled up on the sides in the pigeon-hole manner, and 20 inches across. In these spaces hot-water pipes are made to traverse (*vide* fig. 639, vol. i.), the bottom parts of the spaces being filled up with soil similar to the beds; and the upper part, also 2 feet in depth, is left open that the heat from the pipes may radiate freely and find its way into the pits, which are span-roofed and covered with boarding. The spaces between the pits in which the pipes are laid are covered with Yorkshire pavement to prevent the escape of the heat, as well as from its being comfortable to walk upon. The plants are excited early in December, that a supply may be obtained by the end of that month, the temperature ranging between 50° and 60°. During the forcing period, the plants are assisted by occasional supplies of rich manure in a liquid form. For early forcing this plan is liable, to a certain extent, to the objections stated above—modified to some degree, however, inasmuch as the heat can be maintained at the roots till a late period of the season; and the latent or weak buds may thus be induced to spring and throw up stems, by which sufficient excitement is thrown into the roots to cause them to form a fresh series of buds for succeeding crop. The advantages of the system of permanent beds are held by many as important. It prevents, as they say, the great sacrifice of ground in the production of roots, which require at least two or more years' expensive culture to prepare them for a single return. We should, however, take into consideration the importance of what is called *rotation in cropping*; and for this the destruction of a few beds of asparagus yearly offers an excellent opportunity. In our own case, we have about an acre of ground under this crop for the purpose of forcing alone. This space we have in three sections, one

of which is taken up every winter, and a corresponding quantity planted every spring from the seed-beds of the previous season.

The great supplies sent to the London markets are produced during winter by the taking-up mode, and are for the most part forced upon beds of fermenting material. Our own opinion is in favour of this plan, and next to it that of growing in pits heated upon the principle shown in our improved asparagus-pit, described p. 455, vol. i., and covered with a glass roofing, to be kept on until the reserved stems become fully matured and the buds ripened, when it may be removed until required again the ensuing season.

The London market-gardeners' mode of forcing asparagus is by placing the fully matured roots on beds of fermenting dung, placed in trenches 2 feet deep, having 6 inches of mould to plant in. These are then hooped over, and covered with mats or otherwise to blanch them, and make them look fine and white, to suit the taste of the market. In private families, however, this white colour is no recommendation, a fine healthy green being preferred, and this can only be attained by growing it in the light; therefore the private gardener's practice is the best, and to attain it so, he has to employ glass sashes for protection, and to admit abundance of air during its growth. Mr Cuthill was the first, we believe, who attacked the old and absurd practice of blanching, and his views were aided by several sensible writers in "The Gardeners' Chronicle," and amongst them the talented editor of that paper.

*Amateur forcing.*—Forced asparagus is not, as is supposed, confined to the tables of the rich, and those only who have extensive forcing accommodation. Any amateur who has the command of a cart-load or two of tree-leaves or stable-litter, or who is in the neighbourhood of a tanyard, where he may often get tan for taking away, may have as good asparagus in March, or even earlier, as his richer neighbour; and with the aid of a one or two light frame, he may have it at his Christmas dinner. The way to proceed is, First get your roots, which can often, for so small a supply, be obtained from a neighbour, or bought from a nursery or market-garden. Many amateurs, how-

ever, have their own asparagus-bed in their garden. To those, therefore, we say, Make up a bed in some warm sheltered corner of either of the above materials, and to the thickness of 3 feet or  $3\frac{1}{2}$ , if leaves only be used; set the roots on the surface after the strong heat has declined, imbedded in the soil as stated above, or in leaf-mould or rotten tan; cover them at first only as high as the tops of the crowns, and after ten days lay on 3 or 4 inches more, keeping the surface within 9 or 10 inches of the glass: for, to secure a crop by Christmas, glass will be required for its protection. If for March use, the bed may be hooped over, and covered, first with semi-transparent canvass, which will admit light enough, and therefore may be kept on permanently; while during night and in cold wet days, and during frosts, a waterproof tarpaulin should be put over all, to throw off the wet and retain the internal heat. A very slight heat is all that is necessary. In regard to taking up the roots, amateurs will do well to commence on one side of the outer rows of the bed by digging out a trench, forking the earth as much as possible from underneath the plants, so that they may easily, and without straining or injuring their roots, move them out entirely by thrusting down the fork behind them. Be very careful, at the same time, that the buds about the crowns of the plants are not injured by the fork, or bruised in any way during their removal. Asparagus roots may be planted in boxes, and placed in a warm stable or cow-house, and when the buds have attained the height of 3 or 4 inches, they may be brought out daily into the open air when the weather is at all mild: this is with a view to give a greenish colour to the buds; but where colour is not a consideration, this removal will be unnecessary.

Asparagus is sometimes forced in the beds where it grows by covering the surface early in November with hot stable-manure to the depth of a foot, which starts the buds in about twelve or fourteen days; the beds are divided by 3-foot alleys, which are dug out, at the time of covering, to the depth of 2 feet, and filled with heated dung at the same time. In breadth the beds correspond with that of an ordinary garden-frame, which is placed over

them as soon as the shoots have attained the height of from 2 to 3 inches, at which time the covering over the beds is carefully removed and added to the linings placed in the alleys, which raises them as high as the top of the frames all round. This heat, with a sufficient covering of mats or straw over the glass during the night, is found sufficient for the purpose; and as the glasses are uncovered every day, the shoots become of a fine green colour, and are in a fit state for use by the latter end of the month, or beginning of December. The beds are covered in this way in succession, a three-light frame being placed to the end of the first, and so on every ten days during the season of forcing. When the crop in the first frame is cut, the frame is carried forward, and the surface of the bed covered with dry litter or leaves to keep out the frost, but not to the extent to keep the roots in a state of excitement, as it is desirable they should remain at rest until spring, when the covering is removed, and they are allowed to grow in the open air. The portions of the beds earliest forced in this way are allowed a year to recover their strength, when they are again forced. Those that come in later in the season are forced the following year, and there are instances of this mode where the beds have been so treated for thirty years.

Asparagus may also be forwarded a fortnight or three weeks earlier than it will come into use in the open air, by merely covering the beds, about the end of February, with a frame and sashes, without any other artificial heat whatever; or the *cloches*, or small bell-glasses so much used by the French, may be advantageously employed: they are now being made at most of the large glass-works, and may be purchased at 1s. a piece, if taken in quantities of not less than 200.

*Taking the crop.*—The buds are fit for cutting when from 3 or 4 inches above the surface, when of a fine green colour, and while they are firm and compact, terminating in a close obtuse point. They should never be blanched, although this has been strongly recommended by one who ought to have known better. The French, Dutch, and Germans almost invariably did so, and even put themselves to the trouble of placing an opaque tube over each bud, for the evident purpose of

spoiling it. Were glass tubes used, the crop would be hastened forward, and probably increased in size, without doing injury to the colour or lessening its flavour. No shoots ought to be allowed to exceed 6 inches in length. In proceeding to cut the buds, remove with the side of the asparagus knife a little of the soil from around their base, push the knife gently downwards, keeping it quite parallel and close to the shoot to be cut, taking great care in doing so that none of the buds yet under ground are cut or injured: when the knife is as deep as the base of the shoot, give it a slight twist, pressing it at the same time close to the shoot, and draw it gently upwards, by which process the bud will be separated from the crown. The wound, being ragged, in consequence of being cut with a serrated edge rather than a smooth one like a knife, will not bleed so much, and hence be less weakening to the plant. Fig. 49 shows such an instrument: there are other forms in use,

Fig. 49.

ASPARAGUS CUTTER.

but in no way superior to this. The blade should be thin, about 9 inches in length, with a wooden handle: by being slightly hooked at the point, it is less liable to cut the underground buds, while the serratures on the concave side more readily catch the shoot intended to be cut. Many use only a common pruning-knife, especially when the shoots are to be cut about an inch under the surface; but the cleanness of the wound leaves the sap-vessels open, and a considerable waste of sap is the consequence. A shallow basket should be carried in the one hand to receive the shoots as they are severed by the other, and they should be laid with their buds pointing in one direction, and afterwards carried to the vegetable-house to be washed, dressed, and tied up in bundles of about 3 inches in diameter each, the ends of the shoots cut all to an equal length and neatly placed together, so that no one bud projects beyond another. In this way they are ready for the cook, who, depending on the man who serves the kitchen having properly cleaned them, commits them at once to the saucepan of boiling water in bundles as they

are. In cutting from established beds, every bud, large and small, is cut, and they are afterwards sorted into sizes, one, two, and three, the first being the largest and finest formed, the second of a less size, while all the small, or any that may have the points of the buds damaged or broken off, are placed in the third, to be used for soups, imitation green pease, or the like. This general gathering will often continue for from four to five weeks, after which only a few of the larger should be taken, the rest being allowed to grow for the support of the roots and encouragement of buds for another season. The reason why the whole buds are cut away is, that if a portion of them were left and allowed to grow, they would draw too much upon the roots, and render them unable to continue sending up more; or if they do so, such shoots would be small and worthless. With young buds the case is different; they must not be so closely cut; only a few of the stronger buds should be taken, and even that not continued longer than about a fortnight. By the middle of June in England, and the latter end of it in Scotland, cutting should entirely cease if the future crop is to be regarded; or a bed or two may be gone on with ten days longer, and such beds have a respite the following season. Beds intended to be forced should have very few of the buds cut, if any at all. It often happens, in cold seasons, or in late situations, that the buds come slowly through the ground, and in such cases there is often a number of hard, dry, scaly appendages found attached to the shoots near their base. These should be carefully scraped off with a sharp knife in the vegetable-house before tying up, but on no account should the skin be peeled off. Some, however, prefer allowing the shoots to attain the height of 6 or 8 inches above ground, and then to cut over close to the surface. This is no doubt a very good way when it is growing rapidly, and in that way its full flavour will be attained.

Asparagus may be kept several days after cutting, if their ends be set into a shallow vessel of water, and placed in a dark cool cellar to prevent the buds opening.

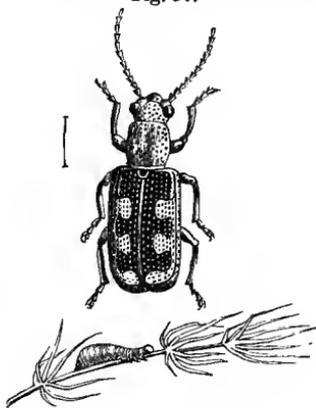

*Approved sorts and their qualities.*—There is only one kind of asparagus, although seed-lists present us with a goodly number of names,

such as Gravesend, Battersea, giant or Grayson's, true Reading giant, &c. No doubt much depends on saving seed from the best plants, as is the case with everything else, instead of gathering it promiscuously, as is too frequently done; and while the prices of seeds are so low as they now are, there is little inducement for the seed-grower to do otherwise.

*Insects and diseases.*—Snails and slugs are often troublesome in mild springs, attacking the buds as they push through the soil: they often attack the stems of the plants when well grown, near to the ground; but they can be readily got rid of by dusting lime over the ground in the evenings. From its caustic property, on touching their bodies it speedily kills them. The wireworm is a much more to be dreaded enemy; it perforates the centre of the buds under ground, and totally destroys them. Piercing the ground amongst the roots with an obtuse-pointed dibber, and pouring about a table-spoonful of spirits of tar into each hole, will kill numbers of them; setting traps of slices of carrots, potatoes, or turnips, attached to a skewer, and burying them close to the tops of the crown, will attract them by thousands, and on drawing them up every other day they will be found attached to them, and may easily be destroyed. This may be considered a tedious process; it is nevertheless a most effectual one.

The asparagus beetle, *Crioceris asparagi*, fig. 50, is often found during the early part of summer depositing its eggs on the stalks. It appears to abound much more in some seasons than in others; and while it is a grievous pest

Fig. 50.

ASPARAGUS BEETLE AND GRUB.

in one locality, it is next to unknown in others. In the year 1836 it abounded in the gardens round London, the larvæ, beetles, and eggs being often detected on the same plant and at the same time. The larvæ feed on the leaves and stems, and are much more destructive to young plants than to older ones. The larvæ are fully grown about the end of June, and may readily be detected, appearing of a dirty olive-green colour, fleshy and shining; in form somewhat cylindrical, narrower towards the head;

tail recurved, holding fast to the plant by a fleshy foot; head small, black and shining; pectoral feet small, and six in number, and set at a considerable distance apart; sides plaited; belly covered with fleshy protuberances. Their larva state is of short duration, continuing only about ten days: as it is only in this state they seem to feed, their numbers and activity must be great to commit much mischief, and hence, perhaps, so little is known of this insect or its habits. It then descends into the earth to undergo its changes. In its pupa state it assumes a curved position, and in the course of three weeks the perfect beetle is formed, when it ascends the plants to deposit its eggs. No very reasonable means has been as yet discovered for its destruction.

*Asparagus copper-web, or fungus.*—This destructive fungus has recently been detected in Cambridgeshire, where vast quantities of asparagus are grown for the London market. It at first appears as a mould, spreading widely and rapidly amongst the plants, killing every one it attacks. It is also found to be destructive to carrots and potatoes. As yet this fungus is only known as a mycelium. It has not as yet been found in a perfect state of fructification, to enable botanists to determine its species. Saffron and lucerne crops have been long ago attacked by a similar, if not the same disease. The origin of this fungus is not known; its effects show themselves as a pale madder-coloured web, and although not visibly penetrating into the substance of the roots of the plants, yet it so completely impedes all communication of the tissues with the external air as completely to impair their vital powers. The only remedy hitherto found effective is to cut a trench round the infected plants, so as to stop the progress of its spreading, as, like most other fungi, it radiates from a centre; and it might be quicklime, if repeatedly applied, would arrest its progress, if not destroy it altogether—few of the fungi resisting its caustic effects.

*General remarks.*—The only certain way of improving this useful plant, is by carefully selecting seed from the finest specimens, growing them from their first stage to their last in highly enriched soil, preserving the roots from injury, and, above all, not cutting too severely. Support the seed-bearing stems during summer, and when the seed is ripe in autumn, cut over the stems and hang them up in a dry airy place till spring, when they may be rubbed or thrashed out of the berries and immediately sown. If for sale, pick off the berries and wash out the seed, allowing them to steep an hour or two in a tub of water, to soften the outer covering. When the seed is extracted, dry them thoroughly in the sun, and bag them till wanted. It is proper to remove the seed-bearing branches before any of the seeds fall to the ground, to prevent them taking possession of the beds and forming young plants amongst the old ones, which causes confusion and overcrowding. Asparagus seed will, if kept properly, retain its vegetative properties for fifteen or twenty years: it has been known to have been kept longer, but as no advantage can arise from this, seed of the preceding year's

growth is greatly to be preferred. Under favourable circumstances, the seeds vegetate in ten or fourteen days.

Its European names are—Asperge in French; Aspergie in Dutch; Sparagio in Italian; Spargel in German; Esparrago in Spanish.

## § 2.—THE ALISANDER.

*Natural history.*—Alisander, or Alexanders (*Smyrnum olusatrum* L.), belongs to the natural order Umbelliferae, and ranks in the class Pentandria, and order Digynia, in the Linnæan arrangement. The name of the genus is derived from *Smyrna*—myrrh; being of similar qualities to that plant. It is a native of Britain, growing near the sea; and from its being often found near the sites of old buildings, it has been supposed that it was more generally cultivated formerly than at present. *Smyrnum perfoliatum*, a native of Spain and Italy, is thought by many superior to this sort.

*Uses.*—The leaf-stalks, when blanched, like celery or cardoons, are the parts used, and were, before the cultivation of the former, used for similar purposes. It is now rarely met with in British gardens, and has been introduced to those of the Continent only to a limited extent.

*Propagation.*—Annually from seed, and its whole treatment is so similar to that of the cardoon as not to demand any general notice.

*General remarks.*—Its European names are—Maceron in French; Macerone in Italian; Smyrner-kraut in German; and Cardo do coalho in Portuguese.

## § 3.—THE CARDOON.

*Natural history.*—The cardoon, or chardoon (*Cynara cardunculus* L.), belongs to the natural order Compositæ, sub-order Carduaceæ, and to the class Syngenesia, and order Æqualis, in the Linnæan arrangement. The generic name is derived from *kyon*, dog; the spines of the involucre resembling dogs' teeth. It is a native of Candia and the south of Europe, and was introduced into England in 1656. It does not appear to have been early or extensively cultivated, many of our older authors taking no notice of it. It is even still only in our best gardens that it is found to have a place. On the Continent it is different; and there not only are the midribs of the foliage used in culinary matters, but the corollas of several parts of the same natural order are employed in various departments of domestic economy.

*Uses.*—The foot-stalks as well as the midribs of the leaves are used for stewing, soups, and even salads in autumn and winter; but to prepare them for these purposes they require to be blanched, and the longer these parts are, and the more rapidly they are grown, the more are they esteemed on account of their greater crisp-

ness, tenderness, and colour. The process of dressing them is thus given in "The Gardeners' Chronicle," vol. i. p. 143:—"When a cardoon is to be cooked, the solid" not piped or hollow "stalks of the leaves are to be cut in pieces, about 6 inches long, and boiled like any other vegetable in pure water (not salt and water) till they are tender. They are then to be carefully deprived of the slime and strings which will be found to cover them; and having been thus thoroughly cleansed, are to be plunged in cold water, where they must remain until they are wanted for the table: they are then taken out and heated with white sauce, marrow, or any other of the adjuncts recommended in cookery-books. The process just described is for the purpose of rendering them white, and depriving them of a bitterness which is peculiar to them: if neglected, the cardoons will be black, not white, as well as disagreeable." They form, in the hands of a skilful cook, an excellent and wholesome dish, deserving far more general notice. One good plant will be sufficient for two or three dishes.

*Sowing and planting.*—Although a perennial in its native country, it is little better than an annual in Britain, and is therefore raised from seed annually, the first sowing being made about the beginning of March, on a very slight hotbed. The principal crop is sown about the middle of April. This is for an English climate; for a Scotch one they should be for both crops reared on a slight hotbed; and, to render their transplantation more certain and convenient, the seeds should be sown in 48-sized pots, one seed in each, and when 6 inches high transplanted at once to where they are to arrive at maturity. This rule is always necessary in Scotland, so as to get them ready for transplanting as soon as the danger of spring frost is over. The seed is pretty large, much after the form of that of sunflower or artichokes. In England it is expedient to sow again towards the end of June, for a late crop to come in during the following spring. Two ounces of seed will sow a seed-bed of 32 square feet. In Scotland it is best to sow always on a slight hotbed; in England, except for the first crop, they may be sown in the trenches where they are to come to perfection, making the ridges 5 feet apart, a foot deep, and the plants 14 inches apart in the line.

*Method of sowing.*—Trenches are dug as for celery; a moderate manuring only is necessary, and that manure should be in a decomposed state, as during the heat of summer copious supplies of water should

be given, to prevent them running into flower, in which case the crop would be rendered useless. As we have before remarked, when water is to be used for such crops, it is no additional labour, and very little more expense, to have it enriched by a little guano. If the seeds are sown, two may be placed together, at the distance of 14 inches apart, one of the plants from which, should both vegetate, is to be removed when about 6 inches high. If transplanted from pots, or from a seed-bed, set each plant at the above distance.

*Subsequent cultivation.*—Water during dry weather. When the plants have attained the height of 18 inches, place a stake 3 feet high to each, and tie the leaves loosely to them, the intention being to prevent their being broken by high winds. Earthing-up the stems should take place at the same time, putting a little often to them. Some do not earth up until the plants have nearly attained their full height, and earth up all at once; others do so progressively, believing that the stalks are, by this means, rendered more crisp, firm, and delicate; whereas, by the other method, they say the stalks are liable to become hard and stringy from exposure to the air; and there is, no doubt, some reason for thinking so.

*Taking the crop, and subsequent preservation.*—By September in England, October in Scotland, the early crop will be fit for use, and the successional crops will continue on till the end of March. The earth is carefully removed, the plant taken up by the roots, and carried to the vegetable-room. The roots are then cut off clean, as well as the points of the leaves as far down as to where they are found solid and well blanched. They are carefully washed, and the parts of the leaf-stalks left are carefully tied to the stem with a broad piece of clean fresh matting, in which state it is ready for the cook. When severe frosts are apprehended, a portion of the crop should be taken up, roots and leaves entire, and carried to the root-cellar and packed amongst sand, laying the plants down in rows and packing the sand around them, one course over another till the bin is full. In this way they keep well, and become more perfectly blanched. The remainder of the crops should also

be taken up and placed on ridges, as will be found recommended for celery. The intention of taking up the plants and laying them on their sides with the points of their leaves inclining downwards, is to prevent the wet and snow getting into their hearts, which would soon rot them; for although naturally pretty hardy, from the luxuriant state in which they have been grown they are very susceptible of injury from frost, and equally so from wet.

*Approved sorts and their qualities.*—1. *The common* or plain cardoon without spines—the *Cardon plein inerne* of the French—is that most generally grown.

2. *Cardon de Tours.*—*Cardon piquant*; *C. spinocissima* of Prest.

3. *Spanish cardoon.*—Of large size, the mid-ribs being very succulent and solid. The *C. integrifolia* of Vahl.

4. *Red cardoon.*—*Cardon à côtés rouges* of the French.

*General remarks.*—A plant saved over winter, and left unblanched, will afford a sufficient supply of seed for a moderate-sized garden. They ripen their seed in August; and seed well ripened and kept will retain its vegetative properties six or seven years. The cardoon of Tours is so formidable on account of its strong and numerous spines, that the workmen, in earthing it up, &c., are said to be protected by wearing a leathern frock over their clothes. Some people, instead of earthing up the plants, envelop them by twisting hay-bands round them, and cover them up with earth only on the approach of winter.

Its European names are—*Cardon* in French and Italian; *Kardonien* in German.

#### § 4.—THE ARTICHOKE.

*Natural history.*—The artichoke (*Cynara scolymus* Wild.) belongs to the natural order Compositæ, sub-order Carduaceæ, and the class Syngenesia, and order Æqualis, in the Linnæan arrangement. The origin of the generic name is given in last section. The English name, artichoke, is derived from the Celtic *art*, a spine, and *chaultz*, a cabbage. London thought it more likely to come from *carcioffo* or *kharchiof*, its name in Arabic. The generic name is also supposed to be derived from *Cinis*, because Columella asserts the land in which it should be grown ought to be manured with ashes. Parkinson says it is so called from the ash colour of its leaves, a far more probable surmise. It is somewhat singular that this vegetable should bear the same name in English, French, German, and Dutch, with very little variation.—*Vide General remarks.* It was held in high estimation by the ancient Romans.—*Vide INTRODUCTION.* The Greeks and Romans appear to have procured it from the coast of Africa, as also from

Sicily. It was brought to England in 1548 from Italy, as Phillips remarks, not Gerard, as erroneously stated in the "Encyclopædia of Plants;" for although he has left us correct representations of both the French and the globe varieties, he makes no mention of their country or their introduction: we may therefore conclude that they were become common in 1596. The same excellent authority remarks, "By reason of the great moisture of our climate" compared with that of Italy, "and the attention which was paid to its cultivation, it soon became so much improved in size and flavour that the Italians sent for plants to England, deeming them to be of another kind, but they soon returned to their natural size when restored to that country." It grows wild in the open fields in Italy, and attains the height of 5 or 6 feet. On account of the great size of the roots, and their penetrating the soil so deep, they withstand the dry hot summers about Paris, where they are most extensively cultivated and most abundantly used.

*Uses.*—The parts used are the lower parts of the leaves or scales of the calyx, the fleshy receptacles of the flower freed from the bristles and seed-down, commonly called the choke, as they are very disagreeable when swallowed. Sometimes, particularly in France, the tender central leaf-stalk is blanched and eaten like cardoons. The bottom, which is the top of the receptacles, is fried in paste, and enters largely into fricassees and ragouts; they are sometimes pickled, and often used in a raw state as a salad. The French also cut them into thin slices, leaving one of the scales or calyx leaves attached, by which the slice is lifted and dipped in oil and vinegar before using. The English present the head whole, or cut into quarters upon a dry plate, the guest picking off the scales one by one, which have a fleshy substance at their base; these are dipped in oil and vinegar and eaten first, the bottom part afterwards with a knife and fork. What is called artichoke chard is the tender leaf-stalks blanched and cooked like cardoons. The Italians and French often eat the heads raw with vinegar, salt, oil, and pepper; but they are generally preferred when boiled, and in this state are sold in the streets of Paris as commonly as baked potatoes are in those of London. They are a favourite dish at a French breakfast, while in Britain we use them at supper. The young heads are pickled whole when about 2 inches in diameter. Medicinally, the stalks are considered aperient and diuretic; the leaves, in their natural state, boiled in white wine whey, are thought beneficial in cases of jaundice, and, when cut into pieces and steeped in sherry wine, an excellent antibilious medicine. The roots were eaten by the ancient Romans sodden in water to enable them to drink to excess, as it excited a desire for liquor; and Athenian mothers desirous of having male children were recommended to eat of artichokes freely.

*Propagation.*—The plant may be propagated by seed, which in France ripens

freely in September and October. It seldom comes to maturity in Britain. But this mode is seldom had recourse to; it is, therefore, multiplied by suckers, slips, or by division of the roots. It is probably on account of our mode of propagation being on the extension principle, and the seed not ripening freely with us, that we have few or no new improved varieties of the plant.

*Planting.*—The suckers or slips are taken from the old roots in March or April, this depending on the season and situation; for it is better to delay a week or two, so that the young roots may be formed on the suckers before they are detached. In taking them off, a little of the earth is removed from the side of the plant, so that the position of the sucker may be seen; it is then cut from the old root with a knife, preserving as many of its young roots as possible. The slips or suckers should, however, not be taken off till they have attained the height of a foot or 15 inches, and be planted as soon after removal as possible. No curtailment of the leaves should be allowed, although a very general practice. They should be planted in rows 4 feet apart, and the plants set 2 feet distant in the line. It is usual to put them in patches of three plants each, but it is better to have one plant only. When the old roots are to be divided, the operation may take place earlier in the season, and when the young plant is only 5 or 6 inches sprung. This is, however, not so good a way as using the suckers without any portion of the old root being retained. Give water at planting, and continue it until they have taken root. The heads will be produced the first season, but later than those from established plants; which circumstance justifies the practice of making a new plantation every year, as it extends the season of the crop. Although artichokes will continue producing abundance of heads for a number of years, if in a good soil, and well attended to with manure, we think it better to plant annually, and so destroy half of the previous stock yearly, thus having strong young plants, and offering an opportunity for changing the soil.

*Subsequent cultivation.*—Keep the ground well stirred up between the plants, thin out all the suckers that arise in spring,

except from three to four of the strongest and best placed. Cut the crop as it is fit for use, whether wanted or not, as allowing them to flower greatly weakens the plants, as does also allowing the stems that produced the heads to remain after the heads are cut off. No plantation should be allowed to continue on the same ground more than four or five years, and the biennial system is the best. When the crop is finished, which will sometimes occur about the end of October or beginning of November, the ground should be heavily manured, and the plants protected from frost by covering the ground around the roots with stable litter, leaves, fern, rotten tan, or finely-sifted coal-ashes. The latter we prefer, as it excludes both the wet and frost better than either. Many dig out the soil from between the rows and bank it up over the roots, which is both a laborious and useless practice. Whichever of these modes is followed, it is essential that the leaves of the plants be not buried. In spring the covering is removed when all danger of frost is past, and before the plants begin to shoot.

Some recommend potting some of the small suckers in autumn, preserving them during winter in a pit, and planting them out in May. This is quite uncalled for, as abundance of small suckers may be obtained from the old plants in May naturally, if they have not been destroyed as they arise from the stools; or a few plants may be left only, moderately thinned for the purpose. Our May-planted crop, by such means, continues to bear till the middle of November. Protection is necessary, as, although it does not often happen in moderate climates that they are killed during winter, yet such accidents have occurred. It is recorded that once, during the seventeenth century, and again in 1739, almost all the artichokes in England were destroyed by the frost, and that they were again introduced from France. In 1814, in Scotland, they were much injured; and again in 1837-8, both in England and Scotland, unless where very carefully covered, they suffered very much. In all cold exposed situations covering is positively necessary, and in most others expedient.

*Soil and manure.*—The roots penetrate to a great depth, therefore the soil should

be deep, well drained, and of a light loamy texture, highly enriched with good manure, and that deposited at the bottom of the trenches, as well as incorporated through the soil during the process of trenching. Few culinary plants, if we except the asparagus and sea-kale, like salt more than this; it should be supplied liberally, and repeated as a top-dressing twice during each growing season. Heads of very large size are produced in the Orkney islands, resulting, it is said, from the quantity of sea-weed employed in the culture. We incline to more than mere supposition, that the cause really is the saline matter carried up from the sea into the atmosphere, and in this way rendered beneficial to the plants. The larger the heads are, the more eatable matter will be formed; and not only that, but it will be more delicate and high-flavoured; therefore, to obtain large heads, strong plants must be produced, and this is only to be attained by allowing them plenty of room for their large foliage to develop itself fully, presenting the largest possible extent of their surface to the atmosphere, from which so very much of their actual food is derived. Young plants of two years' growth, and as rich a soil as can be afforded them for the roots to play their part in, are the conditions necessary to attain this end; and also, when the stalks show many heads, these should be reduced in number to two or three; and when the largest size of all is desired, only one head should be allowed to a stem, and all the small ones forming, on lateral branches, should be removed. A very dangerous recommendation has been given in "The Edinburgh Encyclopædia"—namely, to insure large heads, "the ends of the leaves should be shortened." Than this no worse counsel could be given, inasmuch as the leaves perform so important a part in the collecting and elaborating the food of the plant. Abercrombie, the very best of our old gardening authors, but evidently no physiologist, errs much when he recommends cutting off all the large leaves previous to covering the plants in autumn. We say, let the leaves, large and small, remain and die off of their own accord; for as long as a leaf remains green, or continues to be a living thing, it goes on supplying the plant with food until it becomes para-

lysed by the frost, or dies off when its natural functions are completed. When we look back to the practice of the olden times, it is quite enough to make one shudder to think of the mutilations to which most plants were subjected. Celery and leeks were deprived of the half, and that half the best, of their leaves at planting: artichokes, cardoons, &c., shared a similar fate. Ask the physiologist what is the use of leaves, and whether they should be wantonly destroyed? In deep peaty soils, when well limed and manured, artichokes have been grown to a very large size; and even the recommendation of Columella has, of late years, been revived—namely, to manure them with wood-ashes and salt.

*Taking the crop, and subsequent preservation.*—For pickling whole, and some other purposes, the heads should be cut when about 2 inches in diameter; for the other purposes, when they have attained nearly their full size, but before the scales of the calyx begin to open; for what is called bottoms, when they are at their largest size, and just as the scales begin to show symptoms of opening, which is an indication that the flowers are about to be formed, after which the heads are useless, unless it be for those who use the flowers to coagulate milk, which they have the property of doing; but very few, we believe, make use of them for this purpose. The heads should be cut close from the stalk, in which state they are fit for use. Three to five heads make a dish. If to be preserved for any time after cutting, they should be cut with 6 or 8 inches of the stalks attached to each head, carried to the dark root-cellar, and stuck into a bed of damp sand. They should be taken up from thence every third or fourth day, and a section about as thick as a penny-piece cut off the ends of each, and again replaced. This is to allow a free ascent of the moisture from the sand being carried up through the stalk for the nourishment of the head.

*Approved sorts, and their qualities.*—The English only recognise three sorts, viz., the oval, conical, or French, the large globe, and the dwarf globe. The French, however, possess other varieties; but these are not of sufficient merit to lay great claim on our attention. M. Jacques, formerly one of the royal gardeners at Neuilly, produced plants from seed a year or two ago, the heads of which weighed 2 lb., and

measured 2 feet in circumference, while the whole plant did not exceed 2 feet in height. We believe these varieties have not been received into this country. If this variety remains permanent, it would be a vast acquisition for certain purposes, but evidently too large for the way in which they are usually served up to our tables. The first has its heads oval and green, with the scales open; the second is somewhat larger, globular, and tinged with a purplish colour—the scales are also turned in, or inflexed, at the top; the third is in all respects smaller, but very prolific.

*Insects and diseases.*—The artichoke appears to have no diseases and few insect enemies; and in consequence of this, is considered, in rotation, to be an excellent crop preparatory for onions, carrots, &c., which are so liable to their attacks.

Fig. 51.

ARTICHOKE TORTOISE BEETLE. grub, pupa, and beetle.

Sometimes, however, the leaves are attacked by the larvæ of a very curious small beetle, *Cassida viridis*, fig. 51, which, on account of its being found on this plant, is called the artichoke tortoise beetle. It is found in May and June—is not more than  $\frac{1}{8}$  of an inch in length; the "antennæ are black, the dotted wing-cases and other outer coverings green; the body is black beneath, and the legs pale, with black thighs. The larva has a very flat body, with spines upon its edges; and it has the singular habit of covering itself with its own excrement, which it unites together in a mass, and carries on a kind of fork, attached to its tail. The pupa is also very flat, having thin toothed appendages at the sides of the body, with a broad thorax, prolonged forward into a rounded expansion, which covers its head."—*Cottage Gardener*, vol. iii. p. 317.

*General remarks.*—The European names are, Artisjok in Dutch, Artisehoke in German, Artichaut in French, Cinauco in Spanish and Portuguese, and Carciofo in Italian. The flower of the artichoke, when its florets, which form a noble purple crown, are expanded, have a fine appearance; at which time, if seed be desired, they should be partially broken over, and allowed to hang ten or twelve days with their crowns undermost, to prevent rain from entering, which, in such a mass, is liable to cause rotteness. After that period they may be cut off entirely, and hung upon a dry place, till the seed begins to drop out. It is rarely they ripen seed with us.

When artichokes are to be cultivated for chard, all the leaves are to be cut over in June to within 6 inches of the ground, and the stalks close to it—indeed, if broken over quite low down, the better. Young leaves will be produced in September and October; and when of the height of 2 feet, they should be tied together, but not very closely, and wound round with hay-bands to blanch them; and still farther to encourage etiolation, a little littering matter may be packed round them, secured from blowing away. Some, however, earth them up like

celery or cardoons; and in wet seasons this is the better way, as the crop is less liable to suffer from damp. In six weeks the leaves and their stalks will become completely blanched: they are then fit for use, and should be gathered, and treated as has been recommended for cardoons. This is a process seldom attended to, because in its production the artichoke plants are destroyed, and therefore it should only be practised upon an old plantation, which may be intended to be destroyed at all events. It is, however, a good substitute, should any accident befall the cardoon crop, or in the event of their being neglected to be sown in time.

### § 5.—THE HOP, ETC.

As substitutes for the asparaginous plants already noticed, we may enumerate the following, which, although now not in general demand, have occasionally been used in times past, and may, under certain circumstances, be so again.

*The Hop* (*Humulus lupulus* Wild.) belongs to the natural order Urticæ, and to the class Dicoica, and order Pentandria, in the Linnæan arrangement. The introduction of this valuable plant as an article of culture into Britain took place during the reign of Henry VII.; it was brought from Flanders, where, and also in many parts of Europe, it has been cultivated from time immemorial. It is nevertheless indigenous to Britain: we have found it in the heart of the Grampians. The generic name is derived from *humus*, fresh earth, it preferring such soils. According to the "Encyclopedia of Plants," p. 835, "*Lupulus* is a contraction of *Lupus salictarius*, the name by which, according to Pliny, it was known because it grew among the willows, to which, by twining round them, and choking them up, it proved as destructive as the wolf to the flock." It seems to have been unknown to the ancient Greeks, as it is unnoticed by their authors; and Pliny is the first of the Roman authors who makes mention of this plant. A very interesting account of the introduction and early culture of the hop into England is given in Phillips' "History of Cultivated Vegetables," vol. ii. p. 233.

As an article in the manufacture of malt liquors, it is well known. It is with its relation to culinary purposes we have at present to do. D. Rembert Dodoens is the first who has alluded to this plant as a kitchen herb. He says, "Before its tender shoots produce leaves they are eaten in salads, and are a good and wholesome meat." The young shoots, gathered in spring when about 3 or 4 inches above ground, were formerly used by country people as a substitute for asparagus, which in flavour at least they very much resemble. These sprouts are still to be found in Covent Garden Market, and in the green markets on the Continent are by no means unfrequent.

It is propagated by division of the root—early

in spring. It succeeds best in a deep soil, well enriched. The plants are set in what is called hills, or prepared mounds, at 7 or 8 feet apart, and three or four plants are set in each; but for garden culture, to procure the tops while young, the plants are set in lines 3 feet apart, and the plants 1 foot asunder in the row. They are very liable to the attacks of various species of aphid; hot lime, and, more recently, flowers of sulphur, are applied for their destruction.

*The Milk Thistle* (*Carduus Marianus* L., *Silybum Marianus* Gal.—the Virgin Mary's milk or blessed thistle) belongs to the natural order Compositæ, sub-order Carduaceæ, and the class Syngenesia æqualis in the Linnæan arrangement. The generic name is derived from the name of a plant used by the old Greek writers, not now known; that of milk thistle, &c., from an old dogma that the leaves of the plant, which are sprinkled with white blotches, were so marked by the milk of the Virgin Mary having accidentally fallen upon it. A native of Britain.

*Uses*.—It is not now cultivated, but rises up in most old gardens spontaneously, where no doubt it had formerly been grown, as the young leaves were once used in spring salads, or boiled as a substitute for spring greens. The young stalks, when peeled and soaked in water to extract the bitter taste from them, were cooked and eaten much in the way of sea-kale. The roots, when two years old, are used much in the way of salsify, which they very much resemble, and the receptacle of the flower is cooked and eaten like artichokes. There is little culture required beyond a good soil, in which it luxuriates very much.

*The Cotton Thistle* (*Onopordum Acanthium*) ranks in the same natural order as the last, and also in the same class and order in the Linnæan arrangement. The name is derived from *onos*, an ass, and *perdo*, to consume—because this plant is eaten by that animal: the specific name from its leaves, resembling those of the acanthus. It is erroneously called the Scottish thistle. It attains the height of from 6 to 10 feet, and is densely covered with a white cottony down. Indigenous to chalk pits and fertile lanes.

The receptacle was formerly used as a substitute for the artichoke, and its leaves and their foot-stalks as one for cardoons. It may be cultivated in the same way as cardoons.

The other substitutes for the plants in this chapter are—*Silene inflata* H. K., the bladder campion, indigenous to Britain; *Phytolacca decandria* L., the Virginian poke, a native of Virginia, the tops of whose shoots are eaten as a substitute for asparagus; *Ornithogalum pyrenæicum*, or Bath asparagus—the flower-stems used for a like purpose; *Tamus communis*, or black bryony—also a substitute for the same; *Arctium lappa*, or the burdock—the young shoots also used for the same. The two last may be found abounding in moist rich soils, by the edges of woods, lanes, &c.

## CHAPTER V.

### SPINACEOUS PLANTS.

THE principal of this class of plants are the varieties of the common spinach, and those of the sorrel. There are, however, several others of considerable importance in domestic economy, and to be found in gardens of the highest order, although rarely cultivated in those of minor note. They are less flatulent than many other vegetables, and therefore may, like the common spinach, be indulged in by those who are deterred from using brassicaceous plants, which are exceedingly so. As the chief merits of the tribe consist in the tenderness and succulency of the leaves, the richer the ground is, and the quicker the growth is promoted, the more likely are we to attain this in perfection.

#### § 1.—SPINACH.

*Natural history.*—The spinach (*Spinacea oleracea* L.) belongs to the natural order Chenopodeæ, and ranks in the class Dioecia, and order Hexandria, in the Linnæan arrangement. The generic name is derived from *spina*, a prickle, from the prickly integument of the fruit, or seed, in some varieties. Spinach does not appear to have been known to the ancients, nor is its cultivation traced in Britain beyond 1568, when it is mentioned for the first time by Turner, in his "Herbal," who says, "Spinage, or spinech, is an herb lately found, and not long in use." Its native country is not known; many, however, consider it a native of northern Asia. In spinach we have almost the only instance, among cultivated esculents, in which the male flowers are produced on one plant, and the female flowers on a distinct one.

*Uses.*—The leaves, which are the only part of the plant employed as food, are either boiled by themselves and served alone, or garnished with hard-boiled eggs: in either case it is mashed quite small. It is often used in soups. It is eaten with all sorts of meat; and is, when mashed with butter or rich gravy, much im-

proved by the addition of a few serrel leaves mashed with it. The expressed juice is often employed by cooks and confectioners for giving a green colour to some of their made dishes. When eaten freely it is mildly laxative, diuretic, and cooling. It of itself affords little nourishment. It should be boiled without the addition of water beyond what hangs to the leaves in rinsing them; and when cooked, the moisture which naturally comes from the leaves should be squeezed out before being sent to the table. The young leaves were used as a salad not only in the time of Queen Elizabeth, but even so late as the days of Charles I.

*Propagation.*—The varieties of spinach, being annuals, must be grown from seed.

*Sowing.*—The leaves are required during the whole year, therefore successional sowings become necessary. In England, a small sowing may be made in January if the weather is mild, a larger sowing in February, and a still larger one about the middle of March. In Scotland it is seldom necessary to sow sooner than the latter date, as the winter crop lasts longer with us before running to seed in spring than it does in the south. March may therefore be considered the best time for our earliest crop. Sow afterwards once in three weeks, till the beginning of May, then every week till the end of July. Three sowings should be made in August for winter and spring use, say during the first, second, and third week, each of which should cover a large space, as few winter vegetables are more useful. We always sow two crops during September, as at that period there is ground to spare; and if the crops be not required for other use, they will constitute an excellent green vegetable manure, if dug into the ground in spring. It will be found useful for pigs. The London market-gardeners sow

from the 12th of August to the 1st of September, for winter and spring use.

The seed vegetates in from 10 to 15 days, according to the season; therefore it may be advantageously sown between rows of newly planted pease, beans, cabbage, or the like, as it will be fit to cut off for use before they either injure it, or it prove an impediment to their growth. And when so sown, the drills should be made nine inches wide and the seed thinly sprinkled in them, to give the plants greater room than if sown in the ordinary manner. The germination of the seed may be hastened by its being steeped in water three or four hours previous to sowing; and in sowing during the heat of summer, when the ground is dry, the drills should be soaked with water before the seed is sown.

It should always be sown in drills, 2 inches deep and 18 inches or 2 feet apart for principal winter crops, the plants being, after they come up, thinned to a foot apart in the line. As the object is to have large succulent leaves, the ground cannot be too highly manured. The full-sized leaves should be 8 inches long and 4 broad. For summer crops it may advantageously be sown between rows of pease or similar crops, the slight shade afforded them preventing their running so soon to seed; but during summer the leaves will not attain the size stated above. If sown broadcast, 2 ounces of seed will sow a bed of 120 square feet. If sown in continuous rows, a foot between the summer crops will be sufficient. One ounce will sow 150 feet of a single drill.

*Subsequent cultivation.*—The summer crops should be abundantly supplied with water during dry weather, the plants only moderately thinned, as their duration is short. In November it will be well to thin the plants intended for a winter and spring crop to the above distance in the lines, to clear the ground completely of weeds, and to cover the spaces between the rows with finely-sifted coal-ashes, to counteract damp and to render the ground more comfortable to tread upon during the process of gathering the crop. This also saves the large lower leaves from being splashed with mud during heavy rains.

It is seldom the spinach crop is injured by frosts in Britain, particularly in mo-

derately good situations. There are many places, however, in upland and cold districts, where it suffers much. In such the soil should be less enriched, as the less succulent the leaves are the better they will resist the frost. A more sheltered and warmer place should also be chosen for the winter crop. In some parts protection is necessary, and this, if even of a very temporary nature, will be found sufficient. Sticking the plantation pretty thickly with branches of broom, old pea-sticks, or indeed branches of any kind, so as to break the force of the wind and arrest perpendicular frosts, will, in most situations, be found sufficient; and in such situations, covering the ground between the rows with coal-ashes should be carefully attended to. Still such coverings should not be had recourse to unless in extreme cases, neither should they be applied too early or continued too late in the season. The ground should also be kept clear of weeds, and in gathering the crop the leaves should be pinched or cut off by the foot-stalk, and not plucked or lacerated as is so frequently done, as every leaf so torn and mutilated will almost certainly rot off.

*Soil and manure.*—In light sandy soils spring crops come into use soonest, but they equally soon shoot up to seed and become useless. In strong retentive soils they are later, and continue longer. In medium good garden soils, abundantly manured, the crops succeed best; and it is of importance, particularly for crops to come in during winter and to continue on till spring, that the situation chosen be open and well exposed. The ground cannot be too highly enriched for this crop, and much benefit has arisen from watering the plants with ammoniacal liquor from the gas-works. Pigeons' dung has been used with much advantage, and so also has guano in a liquid form.

*Taking the crop.*—The larger and lower leaves should be gathered first, and these should either be cut off with a knife or pinched off between the finger and thumb close to the bottom of their foot-stalks. It is wasteful and untidy to pluck the leaves off by the middle, and it is equally so to take the heart ones out. The summer crops, as they grow so rapidly, may be cut close to the ground with a knife. When the former is carried to the vege-

table-house the foot-stalks of the leaves should be cut off and the leaves sorted, removing all the flower-stalks should any exist, and rinsing the whole in clean water, placing them afterwards in a clean basket to allow the water to drain from them.

*Approved sorts and their qualities.*—Notwithstanding the length of time spinach has been a very generally cultivated plant, but few varieties have appeared. Indeed, for long only two, the prickly and the round-seeded, were known, and it is only lately that a third has been added. Like the lettuce and endive, this vegetable is divided into two natural divisions—namely, the prickly and the round-seeded sorts.

*Prickly spinach.*—The leaves are much smaller, more round, and less succulent than any of the round-seeded varieties. It stands the winter rather better than they do, and is less liable to run to seed. Readily distinguished by the seeds being prickly, known as winter spinach, being chiefly sown in autumn to stand over winter. Bordeaux, the *Epinard commun*, of the French.

*Lettuce-leaved spinach.*—Of this variety Mr Thompson says: "This is an excellent new variety; the leaves are somewhat rounder than those of the Flanders spinach, of thick substance, and dark green colour. It is, perhaps, not quite so hardy as the Flanders, but it usually stands the winter well, and, from its superior quality, it deserves to occupy at least half the ground allotted to the winter crop of spinach. A variety called *Epinard Gaudry*, if not identical, is very similar to it." It is the *Epinard d'Esquermes*, ou *à feuille de laitue*, of the French. Seeds round.

*Flanders spinach.*—This is an improved variety of the next, with much larger and more succulent leaves often 8 inches in breadth. It is the *Epinard de Flandre*, *Epinard de Flandre à très larges feuilles*, of the French. It is also the principal sort grown in the Netherlands. Seeds round.

*Round spinach.*—This and the prickly-seeded were long the only two sorts grown. Leaves large, roundish, and thick. It is known also as summer spinach, thick-leaved round spinach, spring spinach, round spinach. It is the *Epinard d'Hollande* ou *Epinard rond*, of the French. Seeds round.

*General remarks.*—The European names are *Epinard* in French; *Espinaca* in Spanish; *Spinagie* in Dutch; *Spinaci* in Italian; *Spinat* in German. In Arabia it is called *Hispane*. From this latter name, and as it was formerly often called *Olus hispanicum*, it has been thought to be a native of Spain. Spinach contains a considerable amount of nitre—so much so that the water which is drained from it, after being hoiled, makes as good match-paper as that made by a solution of nitre. In saving seed, as soon as the flowering is past, the male plants, which will have then performed their office, should be all removed to admit air and light to the female

plants to enable them to perfect their seeds. The seed ripens in August and September, and, after being dried for a week or so in the straw, should be thrashed out. Birds are extremely fond of spinach seed, so much so as to render it expedient to cover the seed crop, if upon a limited scale, with netting, from the time the plants come into flower until the seed is ripened. Upon a large scale, boys should be stationed to scare them away. The seed retains its vegetative properties about four years.

## § 2.—WILD SPINACH.

*Natural history.*—Wild or perennial spinach, (*Chenopodium bonus Henriicus* L.) or, as it is called by country people, good king Henry, *tota bona*, and fat hen, names seemingly prevalent over a great part of Europe—the French peasantry, who use it much, calling it *bon Henri*, the Germans, *guter Heinrich*—belongs to the natural order *Chenopodææ*, and to the class *Pentandria* and order *Digynia* in the Linnean arrangement. It is indigenous to many parts of Britain, particularly in loamy soils in waste places. It was formerly grown in gardens for its leaves, which make an excellent substitute for spinach, and is so still in several parts of Lincolnshire. It would make an excellent spinaceous plant for cottagers, and is easily cultivated. The generic name is derived from *Chen* a goose, and *Pous* a foot, the leaves resembling the foot of that animal.

*Uses.*—The same as spinach.

*Propagation.*—Being a hardy perennial, it is increased by dividing the plant into pieces, each having a portion of the root, and a small bit of the crown which is thickly set with buds, which spring freely on being replanted. It may also be propagated by seed sown in March, and transplanted, when the plants are fit to handle, into a nursery-bed. In September following, they should be transplanted into lines a foot apart, and 10 inches in the line, in ground of a loamy nature, and trenched to the depth of 18 inches, as their roots penetrate to a considerable depth. The following spring the leaves are fit to gather for use, and should be picked as they advance, taking the largest first. In this way a bed will continue productive for several years. Most of the species of this genus, both indigenous and exotic, may be safely used as articles of food. It comes into use about the beginning of May, and continues all the summer. Its European names are, *Ganzevoet* in Dutch, *Anserine* in French, *Meldenatrigè* in German, *Anserino* in Italian.

### § 3.—FRENCH OR MOUNTAIN SPINACH.

*Natural history.*—French spinach or Orache (*Atriplex hortensis*) belongs to the natural order Chenopodæ, and to the class Polygamia, and order Monœcia in the Linnæan arrangement. It is a native of Tartary, and was introduced into English gardens in 1548, and long used, as it still is in many countries abroad. It is now seldom seen in our gardens or markets; yet there are some people who prefer it to spinach, and in France it is greatly esteemed.

*Use.*—During the early part of summer, the stems are used; but after that the leaves, which are gathered in succession, and continue producing throughout the season. It is used as a substitute for spinach, having a pleasant slightly acid taste.

*Propagation.*—The seed is sown in drills in February or March, 2 feet apart, the plants being afterwards thinned out to 2 feet in the lines. Sow again for a succession for autumn use in June, choosing a rich, deep, and rather moist soil. There are several varieties, two of which only, the green and purple leaved, are usually cultivated. A plant or two left to produce seed will be sufficient for a large garden. The seed ripens in August.

The European names are, Arroohe in French, Melde in Dutch, Armuelles in Spanish, Meldekraut in German, Atrepice in Italian.

### § 4.—NEW ZEALAND SPINACH.

*Natural history.*—New Zealand spinach (*Tetragonia expansa*, Hort. Kew) belongs to the natural order Ficoideæ, and to the class Icosandria Di-Pentagynia in the Linnæan arrangement. The name is derived from *Tetra*, four, *gonia*, an angle—from the angular form of the fruit or seed-vessel. It is a native of New Zealand, from whence it was introduced by Sir Joseph Banks in 1772. It does not appear to be at all used by the natives. It was, for some years after its introduction, cultivated only as a greenhouse plant; but afterwards, through the recommendation of Sir J. Banks and the Horticultural Society, it began to be grown in private gardens as a substitute for spinach, and may be considered about as hardy as the kidney-bean. It yields a large produce, but by no means equal to spinach; yet during dry warm weather in summer, it will be found in warm localities a useful substitute, as one sowing will keep up a supply, while several of the common spinach have to be made. Indeed, the warmer the weather, the better it succeeds.

*Use*, and its mode of cooking, are the same as the common spinach.

*Propagation.*—Being an annual, it is grown from seed annually.

*Sowing.*—Sow the seed thinly in a pot or pan early in March, which place in a moderate hot-bed till the plants are fit for pricking out; or, to save the latter process, sow in 60-sized pots, three seeds in each, and thin out to one, which, when of sufficient size, and the weather sufficiently warm, plant out on a warm border, or, better, on a bed of soil placed over a slight hot-bed, where they may remain. About the 20th of May in England, or beginning of June in Scotland, will be a good time to plant out without shelter; but if on a mild hot-bed, they may be set out sooner, and protected during night by having the bed hooped over, and covered with tarpauling or Russian mats. Set the plants about 3 feet apart. In five or six weeks after planting, the leaves will be of sufficient size to admit of gathering. Protection will be required in autumn, should it be wished to continue the crop.

*Gathering the crop.*—Pick the leaves off singly, taking care not to injure the points of the leading shoots; they branch out and continue extending till killed by the frost. Half an ounce of seed will be sufficient for the largest garden, and from six to twelve plants enough for an ordinary-sized one. The seed is readily produced, and will retain its vegetative powers for two or three years, if retained in the capsule. It is usually known by its botanic name, and is not more subject to insects or diseases than other plants of the same order.

### § 5.—GARDEN PATIENCE, ETC.

*Natural history.*—Garden patience, or herb patience (*Rumex Patientia* L.), belongs to the natural order Polygonæ, and to the class Hexandria, and order Trigynia in the Linnæan arrangement. The generic name is derived from *Rumex*, a spear—from the shape of its leaves; others say from *Rumex*, a name given by the Latins to a root of thorn; the specific name *Patientia*, from its slow operation in medicine. It is a native of Italy, and was introduced to England in 1573.

There are several species of the genus *Rumex* that have been or are still cultivated; and as their uses and culture are so nearly alike, we shall include them under one head.

The *French round-leaved* or *Roman sorrel* (*Rumex scutatus* L.), a native of France and Italy. Introduced to Britain in 1596, and *Bloody-veined dock* (*Rumex sanguineus*), a native of England, were both formerly cultivated in our gardens

as substitutes for spinach. The former still is, and on the Continent it is grown very extensively.

The common sorrel (*Rumex acetosa*) has been cultivated from time immemorial as a spinach plant, as well as used in salads. In Ireland the leaves are eaten with fish and other alkaliescent food.

The mild-leaved sorrel (*Rumex montanus* H.K., the *Oxyria reniformis* Smith). "The plant is one of those singular individuals which has the character of two distinct genera, and yet is referable to neither. Wahlenberg made it a *Rheum*, Linnæus a *Rumex*, and Mr R. Brown what it now is."—*Ency. of Plants*, p. 295. It is much used in France as a salad, and the male plant of this species is recommended in the *Bon Jardinier* to be planted as edgings. There are several varieties of the common sorrel; that called by the French *l'oseille de Belleville* is the most esteemed, on account of the largeness and succulent state of its foliage. We cultivate it in preference to all the other sorts; and in rich moist soil the leaves attain a large size and thickness. The sorrels are all of great importance in French cookery, and are both agreeable to eat and exceedingly wholesome; and could vulgar prejudice be got over, many an excellent dish might be gathered almost the whole year over from our roadsides. Phillips, in "Hist. of Cult. Vegetables," vol. ii. p. 214, very properly remarks: "Rarity being oftener coveted than excellence, it is not surprising that we should find this native vegetable discarded in an age in which novelty principally stimulates art to furnish our kitchens. The caprice of fashion extends even to our vegetable food; and zeal, which should emulate us to improve the virtues of our own plants, is often wasted in obtaining those of distant countries whose qualities are uncertain. Sorrel is scarcely known as a pot-herb in this country, except at fashionable tables, the small demand having now nearly banished it from the metropolitan markets."

The use of the sorrel is of great antiquity; Pliny observes that it renders meat more pleasant, and lighter of digestion. It is a valuable anti-scorbutic, and is used as an ingredient in salads, and when boiled, as a sauce for roast meat, particularly veal and pork—it greatly assists their digestion. It is an excellent substitute for apple sauce for winter geese, and should, like spinach, be boiled without water. It makes a good substitute for spinach when beat up with butter, and is greatly improved by the addition of the yolk of eggs and cream. It enters into most of the soups and sauces for which French cookery is so famed, and they preserve it in quantities for winter use. It forms as prominent an article in the vegetable markets in Paris as green pease do in those of London. It was held in high repute in Britain about the time of Henry VIII. and Elizabeth. Its use has, however, greatly declined since that time; and yet, amongst all our modern additions, we have not one so wholesome, and of such easy cultivation, or one that would add so much to the sanitary condition of our peasantry, particularly those who live much upon salt provisions.

*Propagation*.—All the kinds may be propagated by seed, which should be sown in rows 18 inches apart, and the plants thinned to 12 inches distance in the line. Sow in March, in deeply-trenched soil, moderately enriched by manure, and rather inclining to damp. In autumn, the old plants may be divided and planted in rows at the above distance. Even fragments of the roots will, if planted, make good strong plants during the following spring and summer. As flower-stalks appear, cut them off. Keep the ground clear of weeds, and annually fork in some rich manure between the plants; or, still better, apply liquid manure without disturbing the roots.

*General remarks*.—The European names of the common sorrel are—Oseille in French; *Acetosa* in Italian; *Sauerampfer* in German; *Accedera* in Spanish; and *Veldzuuring* in Dutch. Those of the garden patience are—*Rhubarbe des monies* in French; *Ronice* in Italian; *Englische* or winter spinat in German.

## § 6.—THE WHITE OR SICILIAN BEET.

*Natural history*.—The white or Sicilian beet (*Beta cicla* L.) belongs to the natural order *Chenopodææ*, and to the class *Pentandria*, and order *Digynia*, in the Linnæan arrangement. The generic name is derived from *Bett*, red, in Celtic; the specific name, according to De Theis, is a corruption of *sciala*, under which name it is spoken of by Catullus. According to Phillips, beet is a name arising from the shape of its seed-vessel, "which, when it swells with seed, has the form of the letter so called in the Greek alphabet." The white beet was introduced to England from Portugal in 1570, where, and also in Spain, it is an inhabitant of the sea-coasts.

*Uses*.—This species of beet—for it is considered botanically as a distinct species from *beta vulgaris*, the common, or red beet—is cultivated entirely for its leaves, whereas the red beet is grown for its roots. These leaves are boiled like spinach, and put into soups; and the midribs and stalks, which are separated from the lamina of the leaf, are stewed and eaten like asparagus, under the name of chard. As a spinaceous plant, the white beet might be grown to great advantage by cottagers and farmers, as it affords leaves fit for use during the whole summer;—but we require as great a diffusion of knowledge in the art of cooking amongst those classes as we do as regards the production of the article to be cooked. The great white or Swiss chard is a large variety of this species; the foot-stalks and ribs of its leaves are dressed like asparagus, and thought equal to that popular vegetable. There are other varieties, differing mainly in the colour of their midribs and stalks, each of which is, however, adapted to

the same purposes. One ounce of seed is sufficient to sow a bed, for transplanting, of 50 square feet.

*Propagation.*—It is best to sow the seed annually, first, in the beginning of March, and again in September—the latter to supply leaves late in autumn and early in the following spring.

*Sowing and planting.*—Always sow in drills, a foot apart for the smaller sorts, and from 15 to 18 inches for the larger. Should failures take place in the crop, the deficiencies may be made good by thinning out where the plants have come up too thick, and transplanting them into the vacancies. The beet transplants well, and therefore, should ground be scarce at sowing time, the seed may be sown in beds, and the plants transplanted afterwards when ground is clear, taking care that in planting the roots be not doubled up.

*Subsequent cultivation.*—Thin the plants when about 6 inches in height to the distance of from 9 inches to a foot apart, according as the sort is large or small.

“In cultivating the Swiss chard, the plants are frequently watered during summer, to promote the succulency of the stalks; and in winter they are protected with litter, and sometimes earthed up, partly for this purpose, and partly to blanch the stalks. Fresh chards are thus obtained from August till May. When the garden sorts of white beet are transplanted, the proper time is during moist weather in May or June. The distance from plant to plant may be from 10 to 14 inches—much of the advantage of transplanting depending on the room thus afforded the plants, together with the general disposition of transplanted annuals, with fusiform roots, as the turnip, carrot, &c. to throw out leaves and lateral radicles.”—*Encyc. of Gard.*, 841.

*Soil and manure.*—The soil requires to be deeply trenched, and of a fair staple quality; and as the quality of the crop depends on the size and fleshiness of the midribs when chard is intended, and on

the breadth and succulency of the foliage when it is grown as a substitute for spinach, it follows that the soil should be rich, or rendered so by copious manuring.

*Taking the crop.*—The largest and fullest grown leaves should be gathered first; others will follow. If grown for spinach, the leaves should be rinsed in clean water, placed in a basket to drain dry, and so sent to the kitchen. If for chard, the foot-stalks should be carefully preserved, and their leaves tied up in bundles of 6 or 8 in each. Twelve stalks, with the leaves entire, will be sufficient for a dish.

*Sorts and their qualities.*—The common white has small roots; the ribs, foot-stalks, and leaves of a delicate greenish-white colour.

The large white, or Swiss chard, has its leaves much larger and thicker; the ribs and foot-stalks and ribs are much larger and much whiter. In those parts of the Continent where this plant is much grown for chard, there are several sub-varieties in cultivation. The green beet, and yellow-rooted varieties of *Beta vulgaris*, are also often grown for a similar purpose. The large Swiss chard is, however, the best. Another variety grown is *Beta maritima* (sea-beet), a plant indigenous to our sea-coast. In seed catalogues we find the following names—Golden-veined, small rooted, green-leaved, red-veined, silver or white veined, commonly called silver beet. Brazilian beet (*Beta Braziliensis*) has very large green leaves, and makes an excellent substitute for spinach, but is rather more tender than the green sort.

*Insects and diseases.*—The beets are not very subject to either the one or the other. The *Haltica nemorum* (the turnip flea-beetle), however, often attacks them, for which see section TURNIP.

*General remarks.*—The European names are—Bette or poirée in French; Biet in Dutch; Acelga in Spanish; Mangold - kraut in German; Biottola in Italian. To save seed, a few of the best formed roots should be selected and kept out of the frost during winter, and planted in a warm well-exposed spot in spring. When the flower-stalks have attained the height of 2 or 3 feet, support them with stakes. The seeds will ripen in September. When dry, thrash them out; and keep them, when thoroughly dried, in paper bags till wanted. The roots of the varieties of white beet are not adapted for the table.

## CHAPTER VI.

### ACETARIACEOUS OR SALAD PLANTS.

THE use of salads is of the greatest antiquity, and, in a sanitary point of view, of great importance, particularly in warm countries. In no country, however, are salad plants more cultivated or used than in France, where they form a very considerable item in the food of the people. The rich eat them as a luxury, the poor from necessity. In Britain, if we except the lettuce, endive, and celery, all of which find a ready sale in our markets—the former during the heat of summer, and the latter during winter—salads, in their greatest variety, are confined mainly to the gardens of the opulent. The artisans in our large manufacturing towns are yearly becoming greater consumers of lettuce, radishes, and celery, in particular, and find benefit from their use. Manchester has long been famed for its celery, and it has been grown to a larger size there than elsewhere. The varieties grown under the name of Manchester celery have long held a place in our seed-lists. The use of salads is only beginning to be appreciated amongst the middle classes in Scotland, and the natural prejudice against “eating green meat” is daily subsiding—a prejudice, by the way, not altogether unfounded, from the coldness of our climate and habits of the people. Salads can only be grown in perfection where vegetation is of rapid growth; and hence, even in England, we do not meet with the same excellent salads as are to be had at every *table d’hôte* in Holland, Belgium, and France.

#### § 1.—CELERY.

*Natural history.*—Celery or smallage (*Apium graveolens* L.) belongs to the natural order Umbelliferae, and to the class Pentandria, and order Digynia, in the Linnæan arrangement. The generic name is derived from *Apon*, water (Celtic), from its growing in ditches and in watery places. Cultivation has transformed it from a coarse, rank, and even more than suspicious plant, to one of the most agreeable and wholesome of all our cultivated esculents. It is a native of several parts of Britain, especially near the sea, and known in its wild state as smallage, but never used by man, and not much relished by other animals. It appears to have been first cultivated in Italy, for in our oldest seed-lists it is called “Upright Italian Celery,” and of this there was a red and white variety. Ray, a writer of older date than any seed-lists, observes “that, if neglected, it degenerates into its first unpalatable state.” Phillips says, “*Ache* is the true English name for this vegetable.”

*Use.*—The whole plant is used either in a green or blanched state, as well as its seeds. In the former, and also in the latter form, it is used to flavour soups. The seeds, at that season when the plant is scarce, are bruised, and put into a small bag to prevent their mixing with the soup; and old seed, that has lost its vegetating properties, is employed for the purpose. In its blanched form it is eaten raw, as a salad; generally served whole, sometimes cut into small pieces, but usually, particularly if large, cut into four quarters longitudinally, for greater convenience in serving it. It is also stewed in white sauce, and is sometimes made into an agreeable conserve. In Italy and the Levant it is seldom blanched, the green leaves and stalks being used either stewed by themselves or as an ingredient in soups. Medically, it is considered diuretic, and a decoction of it has been found good in cases of gravel.

*Propagation.*—Although a hardy biennial in its wild state, it must be considered as little other than an annual in cultivation, unless when grown for its seeds, in which case it is treated as a biennial. It is invariably propagated from seed.

*Sowing and Planting.*—For the earliest crop the seed should be sown by the beginning or middle of February, in pans,

placed on a moderate hot-bed. The seed will often be three weeks before it germinates. When the young plants of this sowing are about 2 inches high, they should be transplanted singly into small 60-sized pots (in decomposed manure only), and plunged in a very slight heat, say  $45^{\circ}$  to  $50^{\circ}$ . By the beginning of April they will require to be shifted into large 48-sized pots, and kept growing slowly till the end of that month or beginning of May, and then planted out in shallow trenches in the warmest part of the garden. Indeed, for those who wish the crop very early, it is well to dig the trenches 2 feet deep, and fill them to within 6 inches of the top with warm dung to stimulate the plants, and cover with hand-glasses, or, better, with longitudinal triangular frames, a foot in breadth at the base, which is open, and a foot in height, having one of the sides glazed. Others grow the plants in pits, shifting them from time to time into larger pots, and plant them out in trenches about the beginning of June, when from a foot to 18 inches in height, earthing them up at the same time, to prevent their leaves being broken. It is only in some families that this routine is necessary. The ordinary earliest sowing is made about the end of February, upon a slight hotbed, either covered with a regular frame and glass lights, or with hand-glasses. Plants from this sowing are once or twice transplanted on a slight heat, in very rotten dung, placed over the heating material about 4 or 5 inches thick, made into a state resembling thick mortar, and beaten firmly down, the plants being at their last removal set 4 or 5 inches apart. These will be fit for final transplanting into shallow trenches by the beginning of June, and will be fit for use in August. A second sowing should be made about the end of March, and if treated as above will be fit for transplanting into trenches by July, and come in for a general autumn crop. And a third sowing should be made about the middle of April, in the open border, or on an exhausted dung-bed, which, when twice transplanted, will be fit to plant out for good about the 10th of August; and as this may be considered the principal winter and spring crop, a much larger sowing should be made. We generally sow a fourth crop in May, to obtain plants for

planting towards the end of September for our latest spring supply. Transplanting is of much importance for securing celery from shooting up to seed, and preventing it growing hollow in the stalks, or pipy, as it is technically termed. The check which the tap root sustains at each removal has a tendency to cause the production of lateral roots, and, as a consequence, the production of greater vigour and rapidity of growth in the plant, and hence a less disposition to run to flower. The object of transplanting on solid masses of rotten dung is to invigorate the plants, and render their future removal safe, as by cutting the dung into squares and lifting each piece entire, the roots are thereby secured from injury, and the plants from any sudden check to their growth. As to the quantity of seed, an ounce will be sufficient for most gardens; but as it is found to be expedient to grow several sorts, the quantities of each must be regulated by circumstances. The London market-gardeners sow for their first crop early in February, again in March, and last of all in April, for their latest crop; the first only of these is sown on slight heat, and hooped over with mats.

Celery-seed should always be sown thin, to secure stocky plants, which never can be the case if they are crowded in their earliest stages. Their first transplanting is effected by using a small dibber or pricker, about half an inch in diameter. Their second removal should be with a dibber at least  $1\frac{1}{2}$  inch in diameter, and cut square across at the point, because at that time the roots will have ramified considerably, and if carefully removed will have small balls of earth or dung attached to them. Their final transplanting should be performed either with the transplanting trowels, figs. 27, 28, or the media they are growing in should be cut into square pieces with a sharp instrument, and, beginning at one end, a flat trowel or small spade should be introduced under the mass in such a way as to keep the ball perfectly entire about the roots. Water must be abundantly supplied during their whole preparatory growth.

Celery is grown in trenches, for the obvious purpose of enabling the cultivator to earth up the plants more conveniently, and hence insuring its more complete blanching. These trenches are

either narrow, intended for a single row of plants, or 4 or 5 feet in breadth, for the reception of several rows of plants. The first is no doubt the best for crops to stand over the winter, where protection is not to be given, and where there is ground to spare. It is the plan adopted to secure very large specimens, and hence the Manchester growers practise it to attain the latter object; and the London market-gardeners grow it in the same way, because, as with asparagus, the larger it is the better it takes in the market. In private gardens, where large size is less a consideration than crisp, well-blanched, and high-flavoured stems, the broad trench, or Scotch mode, is greatly to be preferred, as well on account of its yielding a much greater number of moderately-sized heads upon the same extent of surface.

The London market-gardeners' mode of planting "is to dig out a trench two spades deep, banking the mould up on either side; then to fill in a foot of the strongest manure, such as cow-dung, and to cover this with 3 or 4 inches of mould for planting in. If the ground is very rich, half the quantity of manure is applied. The rows are generally from 4 to 6 feet apart. The plants are then taken from the seed-bed, and planted root and head entire—not trimmed in, a plan which ought to be discontinued in everything." To this we heartily say, Amen. "The plants are placed about 8 inches apart, the intermediate ground being planted with coleworts, lettuce, or any other light crops, which are likely to be off before the celery wants moulding up; but market-gardeners do not begin blanching until the plants are about 18 inches high, as it prevents rain and air acting on the roots."—CUTHILL, *Market-gardening around London*, p. 23.

*The Edinburgh market-gardeners' mode of planting.*—Trenches 6 feet wide and 1 foot deep are dug out; a copious dunging is laid on the bottom, sometimes dug in, at other times spread over the bottom of the trench, trodden or beaten down pretty firmly, and 3 inches of soil laid over, into which the plants are set in rows across the bed, 14 inches asunder, and the plants 9 inches apart in the row. By this means space is economised, and the plants attain a fair average size and quality. The same

plan is very often followed in private gardens; and where the new and improved sorts, such as Cole's, are grown, they arrive at the size most available for family use. This is decidedly the best way for amateurs to grow this crop. They should grow their plants in nursery-beds until they are 10 inches or a foot in height before final planting, giving plenty of water, and afterwards earthing up once a fortnight.

*The Manchester growers* dig their trenches 18 inches wide and a foot in depth, and from 4 to 5 feet distant from each other, and lay in 9 inches in thickness of compost composed of fresh strong soil and well-rotted hot-bed dung, in the proportion of three-fourths of the latter to one-fourth of the former. The plants are taken from the nursery-beds with all their roots entire, and as much ball as will adhere to them. The side shoots or suckers are removed from the stems, and they are set in with a planting-trowel, 10 inches apart, the row being in the centre of the trench. They are watered liberally until fit for earthing up, but not afterwards.

Many plant on the surface—that is, marking out the size of the bed on ground that has been previously trenched, digging in at least 6 or 8 inches of rich half-decayed manure, and planting either in single lines 4 feet apart, or making beds 6 feet broad, and planting across them, setting the rows 14 inches distant, and the plants in either way 8 inches apart in the lines. They may be earthed up as they advance, or not until they have attained the height of a foot. A mode of planting celery, which may be called the simultaneous manner, is practised in some parts, and with evident advantage where ground is scarce. The manner is as follows: Early potatoes are planted in spring (or we would recommend autumn), at about 2½ feet row from row; when they are earthed up, a hollow trench is thus of necessity formed, into which rotten dung is placed, and on that, covered to the depth of 2 inches with soil, celery plants are set. As the potatoes are taken up, a little earth is put to the celery, which goes on growing, so that when the potato crop is cleared, the celery one is well advanced, and treated in the usual manner. If the supposition be correct, that tubers increase in size after the haulm has been

cut, this might be a profitable method of growing celery, by cutting off the haulm of the potatoes when it began to interfere with the celery plants, and thus giving them all the advantages of light and air, the potatoes to be taken up afterwards when ripe, to admit of the celery being earthed up.

It has been suggested to grow celery in water-tight trenches, with a view of supplying them with abundance of moisture at their roots, for there is no doubt that celery cannot be grown rapidly or of large size if kept very dry at its extremities; on the other hand, there is the danger to be apprehended of restoring to the plant its deleterious, nay, poisonous properties, which it, along with so many more of its near allies in the Umbelliferae, is so well known to possess. It were better to adopt a system of subterranean irrigation with liquid manure, to be used only in very dry weather, and only when the plants are in their height of growth, and dispensing with it afterwards. We have adopted the following plan with advantage to the bulk of crop, and without any evident sign of lessening the wholesomeness of the plants: Along the centre of each single trench, imbedded in the manure, and over which the plants were set, we placed a course of drain-tiles laid on soles, having at the upper end (for the ground was considerably on the incline) an upright drain-pipe communicating with the tile-drain below. Into this liquid manure was poured, and allowed to escape through the openings between the tiles, thus moistening the dung and soil in which the roots were growing without at all wetting the soil around the stalks, which should be at all times kept as dry as possible.

*Subsequent cultivation.* — This consists chiefly in carefully removing any side shoots that may arise from the collar of the plants before earthing up, which is of considerable advantage in securing well-grown heads. As to the time of earthing up, opinions of late years seem to differ widely; some advocate the old method of earthing up progressively, putting a little only at a time, taking care to keep the hearts of the plants clear of soil; others say that no earthing up should take place until the plants have nearly attained their full size, when the earth should be

put to all at once; while others earth up when the plants are about 18 inches high for the first time, adding a little afterwards so long as the growing season continues.

Some, instead of using the natural soil of the garden, pack the plants around with fine sand, and others use finely-sifted coal-ashes for a like purpose. Mr Roberts, a year or two ago, recommended what he called his "celery-blanching tiles," which in principle were nothing other, except in price, than common drain-tiles, one of which he placed on each plant, with a view to blanch it, and at the same time to keep it from coming into contact with the damp soil. The idea struck us as sufficiently feasible, believing that etiolation would be effected, and that the protection afforded by the tiles would tend to preserve the plants during winter. We contented ourselves, however, with employing two common horse-shoe drain-tiles, placing one on each side of a plant, and thus forming as good a blanching-tile as the other. These were put on when the plants were about 18 inches high, and kept in their places by working earth in amongst them to keep them steady. Contrary, however, to expectation, we found the beds so treated the first to suffer from rot, and have since discontinued their use for this purpose, although we use them for another, which will be noticed below.

The grand secret, if we may make use of a word which is too often made use of as a cloak to imposture, is to earth up only when the plants and the soil are as dry as possible. To do so when either is damp, is entailing destruction on the crop.

The London market-garden practice is thus described by Mr Cuthill: "The operation of earthing up is all performed by the spade; no hand earthing is employed. Parallel lines are stretched on each side of the row 18 inches from the plants, and the mould is cut out of the alleys to form the blanching ridge. Late earthing up is effected in about three different times."

In earthing up the broad or Scotch form of beds, the plants being disencumbered of all side shoots or suckers, two pieces of board about 9 inches in width are placed one on one side of a row, and the

other on the other side of the adjoining row, or, as "the knights of the whip" would say, one on the near side and the other on the off side of the space between two rows. These boards are placed inclining rather outwards at top; they are kept in their place by a triangular piece of board placed between them like a wedge at each end of the boards, while a man on each side of the bed breaks up the soil finely, which has been left between the beds on purpose, and throws it in between the boards as high as the present earthing up is intended to be carried, which, upon an average, is 6 inches. The boards are then lifted gently upwards, and the pulverised soil falls in between the plants. They are removed to the next space, and so on. This is an expeditious mode, and with very ordinary care none of the soil falls into the hearts of the plants. Others take the leaves of a plant in one hand, holding them together, while with the other they press the soil around their stems; but this is a time-killing process. Whichever process is followed, the soil should be kept open and loose around the plants, to prevent unnecessary pressure as well as exclusion of air.

The following mode of earthing up is detailed by Mr Duncan of Basing Park, in the "Journal of the Horticultural Society," vol. vi. p. 214 :—"The process is effected by three different operations. The first takes place when the plants have grown 9 or 10 inches in height. The small leaves immediately above the roots, and all embryo suckers, are carefully removed. After that the bed is completely saturated with liquid manure;" but subsequently to this period Mr Duncan "does not consider it requisite that any artificial watering should take place. The beds are then covered with about 4 inches of mould from the ridges, which helps to keep the plants in an erect position, and acts like a mulching on the roots, thereby preventing, in some measure, the evaporation of moisture from the bed. Some three weeks before the early crop is required for use, the second earthing takes place, which is performed in the following manner by two operators: Two boards, some 8 or 9 inches in depth, and equal in length to the width of the bed" (for Mr D. adopts the broad trench, or Scotch form), "are placed

edgewise between the rows, each board resting against the plants in either row, so as to form at once space for the reception of the mould, and a protection to the leaves whilst the operation of earthing is being performed. When the required quantity of soil has been deposited, the boards are carefully withdrawn, and placed betwixt the next two rows; and so the work proceeds, until all has been completed. When the soil is of a very wet, tenacious character, dry ashes, fine mould, or other material, can readily be introduced next the plants, for which purpose double boards, properly adjusted and fixed to each other, form a ready medium by which to introduce the material. When sufficient blanching material has been deposited, the boards are carefully withdrawn, and placed in the opposite row; and it will be readily understood that the fine mould which has passed through the vacuum formed between the boards will be in immediate connection with the leaves of the plants, the common earth placed in the centre of the row enabling it to maintain that position. These boards can of course be set to any required distance apart, that distance being determined by the quantity of blanching material at command. This mode, whether applied to single rows or the more economical system of bed-culture, I consider to be at least equal in its effects to any advantage that can be derived from the use of tiles."

The third and final earthing of the early crops is accomplished at intervals of ten or twelve days before the celery is required for use, placing the mould high and close about the leaves. "I have, however," Mr Duncan observes, "found a different system to be advantageous with celery intended for winter use. Some time towards the latter part of October, when the weather is dry and favourable, the plants are fully earthed up; but the soil is neither put so high, nor is it so closely packed to the leaves, as is recommended for the earlier crops, as I have found it to keep better under such conditions. After the winter has fairly set in, I have a sufficient quantity for a fortnight's consumption covered over with leaves which had previously been heated, from which cause they will readily remain in flakes of some 6 inches in thickness, and resist alike the action of

frost and moisture. The covering over of a day's consumption is merely removed with a fork so much farther on to the bed, and this takes place from day to day. When, however, severe frost sets in, the whole of the ridges are covered over in the same manner; but the protection is removed on the recurrence of favourable weather, in order that the plants should not suffer from being too closely excluded from the atmosphere."

*Soil and manure.*—From the nature of this plant, the soil is of little consequence to it, except just that into which the roots are running; and this is in general prepared for them, as will be seen from what has been said above regarding the formation of the trenches, which, we repeat, cannot be made too rich with well-decayed manure. We avoid, however, rank dung, such as is used by the market-gardeners around London, which has a tendency, while it enables the plants to attain a large size, to render them, as they mostly are, tough and woolly. We use very decayed manure, and, until earthing up takes place, supply the roots with liquid manure poured in amongst them, and afterwards by the subterranean irrigation also noticed above; and the best manure we have found for this purpose is guano, with a little salt added, or water richly impregnated with soot or pigeons' dung.

*Taking the crop and subsequent preservation.*—Always begin at one end of a row or bed, taking the plants up by the roots, and carefully avoiding bruising the stems or breaking the leaves. Cut the roots off, and bury them in the trench, but remove the plant otherwise entire to the vegetable-house. Remove the loose outer leaves, and lay them by themselves, to be washed clean, should they be required for soups. The best parts of them, being cut out and cleanly washed, are sufficiently good for the stock-pot, or for flavouring soup given in large quantities to the poor—a mode of disposing of the fragments of kitchen stuff we would like to see more generally practised. The centre and solid part of the head should be carefully examined, and every portion that appears to be discoloured removed; and when washed quite clean, they should be dipped in clean salt-water, to dislodge any small worms which, in mild winters, are apt to find their way into the very

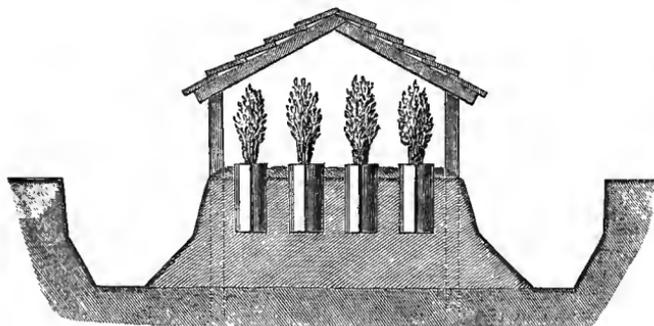

heart of the plant. Almost all vegetables should have a dip in the salt-water vat, if only for precaution's sake. The young gardener should recollect that in the self-same state in which he carries the celery from the vegetable-house it is laid upon his employer's table, and therefore he should make himself acquainted with the form used by the family, for there are various ways of dressing it.

As frost sets in, a quantity of the crop for immediate use should be taken up carefully, retaining the roots and what soil may be attached to them, and tying the leaves together, carrying them on hand-barrows (which is the best way to prevent their leaves from getting broken) to the root-cellar, and laying them in amongst sand—not, however, too dry, else it would absorb the moisture too rapidly out of the leaves and stalks, and render them tough and ultimately useless for salads. From time to time during winter this should be attended to; and in the event of not having the convenience of a root-cellar, or, far better, of a vegetable-house (such as fig. 677, vol. i.), which we consider the best of all structures for the preservation of such crops during winter, supplies should be brought in; for, irrespective of preserving the crop from frost and wet, and being more comfortable for the man who serves the kitchen, it prevents the ground from being poached, and leaves it in a tidy state, which, according to the usual practice, it is not.

We have adopted two methods to insure its preservation during winter, either of which we have found to answer our utmost expectation. We grow most of our celery in what is called the Scotch fashion—that is, in trenches from 4 to 5 feet in breadth, setting the plants in rows across, and at such distances apart as accord with the size we wish the plants to attain. Following the London market-gardeners' practice, we do not earth up until they have attained nearly their full size, at which period we earth them up as high as can be done without burying their hearts. Should the weather continue mild, we give them a little more towards the middle of November, at which time, and when the leaves are perfectly dry, we tie them up loosely, and place a common drain-tile on each side of every

plant, to protect the leaves above where they are covered with the soil, putting in only as much soil between the tiles as will keep them steady in an upright position. We then bank up the sides of the trench, as shown in the annexed cut, fig. 52, along the sides of which we drive in upright posts, 3 inches square, and of such a height as will carry a roofing of boards laid in an

Fig. 52.

MODE OF WINTERING CELERY.

imbricated manner, a few inches over the top of the plants. These posts are set 10 feet asunder, and exactly opposite each other; and their tops are connected with coupling of lighter scantling. The roof boarding is then laid on, and nailed to the couples, which ties the whole roofing together. By this means the rain is thrown off, and falls into the deep trenches between the beds. Should the weather set in severe, we introduce a little light dry littering matter amongst the tiles, and nail a couple or three courses of boards along the sides; but this is seldom found necessary with us, although in many colder localities it will be of advantage. This side-boarding should only be used in very severe weather, as its absence permits a free circulation of air to blow through. The boarding which covers the roof is the portable wooden copings we use for our wall-trees, and which, during winter, would otherwise be laid past in the store-sheds. The posts and coupling are used for a variety of purposes during summer, such as supporting netting over single rows of gooseberries and currants, to preserve them from birds, temporary roofing over out-of-door summer mushroom-beds, &c. Neither the posts, couples, nor boarding are ever cut, as we construct such

temporary erections always of the same size.

The other mode of preserving celery to which we have alluded is even much simpler, and within the reach of every one. We first form a triangular embankment of soil, the sides sloping to something like an angle of  $45^\circ$ . These sides are made smooth, and are each in length somewhat more than the depth the celery plants have been already earthed up to. In November, when the growth has ceased, the plants are carefully taken up with balls about their roots, a few of the lower and coarser leaves are removed—they are now of no further use—and the plants are laid side by side along each of these sloping banks, their roots

being placed at top, and their leaves pointing downwards, with the view of preventing rain or snow getting into their centres. When one course is laid along each side, soil is laid over and between them, to the extent of preventing any part of the one plant touching the other. The surface is again rendered even, and a second row laid on in like manner, taking care, however, to place the roots of this second course 6 or 7 inches higher than the last, or to select shorter plants; the intention being, in either case, to prevent the leaves of the top course resting on those of the lower. Indeed, it is a good plan to introduce a few branches between the two courses of leaves, should they appear too crowded, to admit a circulation of air to pass through amongst them. These are covered the same as the first, only to a greater depth, and the whole finished off much in the form of a potato pit. Should severe frost or much wet set in, we thatch the whole over with coarse littering straw, as far down only as where the leaves of the top course protrude through the soil. To thatch the leaves over would only tend to cause them to rot, for we have found in mild winters that they have continued to grow as well as if they had been allowed to remain in their ori-

ginal position, if not better. The principle in either case is the same—keeping the plants dry, and preventing snow and rain from falling into their hearts. In cold wet soils, we think it would be an improvement to pack the plants, after being laid on the inclined banks, in finely-sifted coal-ashes, or in sharp river-sand. The operation in both cases should be carried on when the plants and the soil are moderately dry.

*Approved sorts and their qualities.*—Of this vegetable there are two pretty distinct classes, namely, the red solid and the white solid.

*Cole's superb red.*—This is comparatively a new variety of great excellence, surpassing, we think, all others in solidity and flavour. Not that it is like the immense celery grown for the market or for exhibition purposes, which is too often more fit to look at than to eat; but it is of a size such as is required for a gentleman's table, averaging, if well grown, about 6 lb. per stick (for stock, head, and stem may be considered synonymous terms in speaking of the blanched part of this plant). It has also the remarkable property of not piping, or becoming hollow or stringy, and has been known to stand twelve mouths without running to seed. It is also extremely hardy. Mr Thompson, however, in estimating the comparative merits of this family, says that red solid, *alias* new large red, new large purple, new Russian, Cole's red, Cole's superb solid red, stripped solid, Violette de Tours, are the same thing, and so also is the Celeri violette, the seed of which has been for several years distributed by the London Horticultural Society as the very best red celery. The Manchester red is believed by him to be scarcely different, and may be considered the same variety, excepting that it has acquired a stronger habit and rounder stalks. Shepperd's red is now preferred to the Manchester red by the prize-growers, because of its flatter stems, and its consequently blanching better. In fact, he reduces all our red varieties to one, the type of which is the red solid.

*Cole's superb white.*—Differing only in colour from the last.

*Manchester giant red.*—One of the largest sorts grown, and excellent for soups and stewing, but far inferior to the last in point of flavour as a salad. It is grown largely for the market.

*Old solid red.*—An excellent old sort, if it can be procured true. It used to be much grown by the market-gardeners about London; but they have since substituted another of far inferior quality, merely because it comes earlier into use.

*Sutton's solid white.*—A very large yet solid-growing sort, exceedingly white and crisp. We believe it originated a few years ago with the Messrs Suttons of Reading.

*Lion's paw.*—A short broad flat-stalked variety, of excellent quality, very crisp, and white.

*Nutt's champion.*—Originated with Mr Nutt of Sheffield within these few years. It attains,

under good management, a very large size, and is, for its size, of excellent quality, very white, and not apt to run to seed.

*Seymour's white champion.*—This is an improvement of other white celeries raised by Mr Seymour. The number of years they have sustained their popularity is the best proof of their excellence. The stalks are broad, flat at the base, closely overlapping, and forming a compact, well-blanching crisp heart.

To the above sorts Mr R. Thompson adds—

*White solid, alias* fine white solid, Celeri Turc, Celeri plain blanc.—Of strong and rather tall growth, blanches readily, and comes into use earlier than the red solid varieties.

*Italian, alias* upright Italian, upright, large upright, giant, Patagonian.—Tall, strong, erect, deeply furrowed; not so crisp as Seymour's.

*Wall's white.*—Is an improved variety of the Italian, which is esteemed by the growers for competition.

*Curled white, alias* Nain frize.—Leaves much curled, resembling parsley, and, like those of the latter, might be employed for garnishing; it is dwarf, hardy, and crisp, but not fine flavoured.

*Early dwarf solid white, alias* Court hatif, Celeri Turc of some.—Dwarf, but very solid, and forms a compact heart; excellent for early use."

In estimating the difference between the eating qualities of red and white celery, it may be stated that the latter is preferred by most people of taste, on the plea that red celery is ranker in flavour, especially when cooked, than the white varieties; and, when served as a salad, the same opinion is entertained by many. Again, as to the difference between large and moderately-grown celery, the case stands pretty much the same, large celery never being so crisp and tender, or so well-flavoured, as that of medium size, provided both have been equally speedily grown.

*Diseases and insects.*—In some soils, those abounding in iron in particular, celery is apt to canker, for which there seems no remedy except changing the constituents of the soil. A parasitic fungus has long been observed to attack the leaves when about half-grown, which is considered by botanists to be *Puccinia Heraclei* Grev. Another has made its appearance within these three or four years, of which we have been unable to gain any information. So serious was it with us in 1851, that we had many hundred plants to throw away to prevent its spreading farther.

The celery or parsnip fly (*Tephritis onopordinis* Fab.), fig. 53, seems its chief enemy amongst insects. They breed in the leaves, and from the blotched appearance they cause, the leaves affected may readily be cut off and burned before the maggot is formed, for it is in that state that it is most to be dreaded. It is thus described in the "Cottage Gardener," vol. 1. p. 73: "If the withered parts (of the leaves) are examined, and the cuticle or skin of the blisters is raised, there will be found beneath it some small green grubs, which have eaten away all the green pulp or parenchyma of the parts so withered. These

grubs are the larvæ of *Tephritis onopordinis*. The grubs may be found in the leaves of the

the substance of the stem ; so that we have no doubt portions of the stalks, although contain-

Fig. 53.

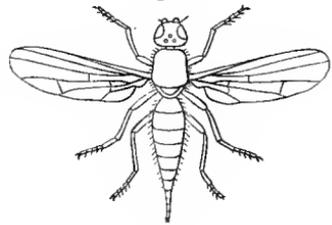

CELERY-FLY, GRUB, &amp;c.

celery in June, July, August, September, October, and November, for there are two or more broods of them in the course of the year. The grubs, although less frequently, are found doing similar damage to the leaves of Alexanders and parsnips. When full grown, the grubs descend into the earth, and remain in the chrysalis state till the spring following, when they give birth to the fly. Then the celery-fly may usually be found upon the leaves of the laurel, hovering over flowers, and resting upon palings in the sunshine, from the middle of May to the end of July." Mr Westwood thus describes it : "The general colour of the body, which is five-jointed, varies from rusty brown to shining black ; head buff, with black hairs ; legs yellow ; thorax (throat) sprinkled with long black hairs ; wings black, with various pale spots ; eyes green. The whole length of the insect is not more than one-sixth of an inch, and its wings, when outspread, barely half an inch across." Mr Westwood suggests that a string smeared with bird-lime, and stretched over the celery plants, might catch many of the parents. This is a good idea, and, if carried out, would no doubt entrap many moths and butterflies also, which would be a wholesale mode of lessening the numbers of grubs afterwards.

*Piophilæ apiæ* (the celery stem-fly), fig. 54.—The discovery of this hitherto undescribed insect is due to the author of the article "Entomology," in the "Gardeners' Chronicle," 1848, p. 332, who thus describes it, and its mode of operation : "The larva burrows into the solid stem and fleshy stalks, working its way up the latter, its tract, as well as itself, being at first almost invisible, from its similarity in colour to

Fig. 54.

CELERY STEM-FLY AND GRUB.

ing the grub, are often eaten, owing to its presence not being suspected. The eye of the entomologist, however, especially if assisted by a moderate lens, easily detects the unwelcome visitor, which may indeed be expected when the solid part of the stem shows traces of being worm-eaten. It would seem, in fact, that it is in the solid part that the injury is commenced, the grubs eating upwards into the more succulent stalks of the leaves, leaving their traces in the former visible in their tracts, which become rusty red, owing to the action of the moisture and air upon the grooved surface which they have quitted. By careful examination and removal of the leaves, the authors of the mischief may be found in their burrows, in the shape of glossy white cylindrical grubs, with a slight yellow tinge, having the anterior part of the body pointed, and the hind part obtusely rounded, and marked with two black points, from whence proceed two delicate air-vessels, appearing like threads of gold beneath the transparent skin, and which run along the whole length of the body as far as the segment immediately behind the head, where they form two minute excreted appendages. The hind joints of the body are indistinct, but the fore ones are more distinctly to be traced. The mouth consists of a black horny apparatus, capable, as well as the head itself, of being withdrawn within the subsequent segment, as far as the two excreted lobes of the air-vessels above mentioned.

"The fly very closely resembles that reared from the cheese maggot. The thorax and abdomen are entirely jet black, and very glossy, with a very slight brassy tinge, and with fine golden grey hairs scattered over the body. The head is chestnut-coloured, paler near the mouth, and black in the middle above. The eyes and club of the antennæ are pitchy ; the bristle of the latter luteous, or yellowish. The legs, including all the coxæ or joints by which they are attached to the body, are very pale straw yellow ; the tarsi, especially in the hind feet, some-

what more dusky. The wings are entirely hyaline and colourless, with the veins very pale buff."

*General remarks.*—The European names of celery are—Appio in Italian; Sellerie in German; Apio hortensis in Spanish; Sellery in Dutch; and Celeri in French. The seed will keep for ten or twelve years. In saving seed, it is better to select some of the plants from the seed-bed, and to grow them without blanching, transplanting them again in spring, and placing them in a warm well-exposed part of the garden, growing if possible only one sort in a season. The side suckers should be removed, and seed sved only from the best umbels. The seed ripens in September, and, when thoroughly dried in the heads, should be thrashed or rubbed out, and bagged for use. A considerable prejudice exists with some people as to the colour of the heads—some preferring the red variety, while others will only have the white. The preponderance is, we think, in favour of the latter.

The management of Mr Cole, who raised the variety that heads our list, is to the following effect, and will be better understood in a separate paragraph, than had we divided his instructions into our different heads. His principal crop is thus produced: The trenches are dug out in the usual manner, 4 feet apart, and manured with the spent dung of an exhausted mushroom-bed. The seed is sown the second week of February upon a slight hot-bed. When the plants are strong enough, they are pricked out in rich soil under hand-glasses, and are removed, with balls of earth, into the trenches, in the first week of June, and set 9 inches apart in the row. At planting, as is usual, they received a copious watering, to prevent the possibility of a check. In earthing up, a medium course is adopted, neither too frequently nor too much at one time. About a month after planting, a slight earthing up is given them, they having been previously well watered with liquid manure or soot-water the day before this earthing takes place. Soot-water is given as a manure, and dry soot is sprinkled along the rows, to prevent the operations of worms. In regard to Mr Cole's success in growing celery, it should be stated that the garden is of a boggy subsoil, and below the level of an adjacent river, which accounts for the absence of watering, upon which most cultivators depend so much—he watering only once or twice after planting. He admits, however, that in dry or elevated situations it is almost impossible to give too much water, and would prefer giving a good soaking once every fortnight to watering more frequently and in smaller quantities. Very rich dung, he remarks, is not good for celery, and strong manure-water should be avoided. It has been imagined, pretty generally, that bad management made bad celery, and especially planting it in too rich soil, to induce extra luxuriance. This opinion Mr Cole dissents from so far; and we believe that he is right when he says—"The bad quality of celery is attributable to the bad kinds grown," and asserts that no person could grow this kind of celery, which has been named

"Cole's superb red," so as to make it either pipy or stringy, or inferior in flavour. In regard to the effect of culture, he says that "late earthing has more to do with making celery stringy than anything else, as it is quite certain that, if the leaves of celery are exposed to full light and dry air for a length of time, the tissue will become harder than if the leaves were grown in comparative darkness. We need no stronger proof of this than the acrid flavour of the outer as compared with the inner leaves of the same celery—a fact demonstrating that, if the leaves are exposed for a long time, they acquire an acrid flavour, which no blanching can wholly remove. For an early crop he sows in heat early in January, and pricks the plants out upon a slight hot-bed; for a second crop, in February, in heat, as before directed; and for a late crop, in March, in the open ground."—*Jour. Hort. Soc.*

Mr Cole believes that this celery could be grown to the weight of say twelve pounds, were it desirable to have it so; and for this purpose he would plant in trenches 18 inches deep, and the same in breadth, and use a compost of turfy loam, peat, and leaf mould, or thoroughly rotted cow-dung, in about equal quantities. He would also place the plants 18 inches apart in the row, and keep the soil well stirred between them during their early growth.

## § 2.—CELERIAC, OR TURNIP-ROOTED CELERY.

*Natural History.*—Celeriac, a sub-variety of the last, is used for most purposes like the common celery, but is much hardier, and differs from it in having a considerable-sized swelling on the stem close to the surface of the ground, which is the part chiefly used, although the leaves, which are much smaller than those of celery, are also used in soups, &c. It is much cultivated in the north of Europe, on account of its root, which may be kept in good condition for use throughout the winter: this the common celery cannot be with them, on account of the inclemency of the climate.

*Use.*—The bulbous-looking form which the root presents above ground is cut into slices, and used in German salads. This, as well as the leaves, is cooked like other celery, only they are less delicate to eat. It is not in very high estimation in Britain, although a few years ago the London markets were supplied with it to a considerable extent from the Continent.

*Mode of propagation and season of sowing.*—The same as for celery.

*Planting.*—The transplanted seedlings are removed from the nursery-beds, and planted on the surface (not in trenches) in moderately enriched soil. They should be set in rows 18 inches apart, and a foot from each other in the line. At planting, all the embryo suckers or side shoots should be rubbed off—a precaution to be

kept in view throughout its growth, as the energies of the whole plant ought to be directed to the formation of the bulb-like root.

*Subsequent cultivation.*—Keep the ground thoroughly stirred up between the rows; and when the bulbs have nearly attained their full size, they should be covered lightly with soil, to blanch them white, and to render the outer coating of their skin more tender. In warm dry weather give abundance of water, to encourage the swelling of the bulbs, for on their size and tenderness their merits depend.

*Taking the crop, and subsequent preservation.*—The crop will be fit for October; and in November, upon the appearance of severe frosts, they should be pulled up, with their leaves attached, and planted, in sand somewhat moist, in a cold pit covered with wooden shutters, where they will continue a sort of existence through the winter, and become somewhat intenerated by absence from light and moderate humidity. The usual practice is to cut off the leaves and bury the bulbs in pits under ground.

*General remarks.*—Seed is saved in the same way as celery, and may be employed for the same uses. It retains its vegetative property ten or twelve years. It is the *Celeri-rave* of the French, and the *Knott-cellerie* of the Germans. It is also called *Knob-celery*, *Knoll-celery*, *Celeri navet*. There is also a sub-variety veined with red, and another with curled leaves, or *Celeri-rave à feuilles frisées*.

*Insects and diseases.*—*Celериac* is liable to be attacked by the celery-fly, *Tephritis onopordinis*, (which see.) We are not aware that the roots have hitherto been attacked by the *Prophila apii*, which has of late years been detected in the stems of celery.

### § 3.—THE LETTUCE.

*Natural history.*—Lettuce (*Lactuca sativa* L.) belongs to the natural order *Compositæ*, and sub-order *Cichoracææ*, tribe *Lactucææ*, and to the class *Syngenesia*, and order *Æqualis*, in the Linnæan arrangement. The generic name is derived from the Latin *Lac*, milk, from the milky juice which abounds in most of the genus, and has been of much importance in medicine. That of *Lactuca verosa*, for example, is highly narcotic, and has been even employed with great advantage as a substitute for opium. The production of the opium qualities, which exist in all this genus, is much lessened by cultivation, and especially by blanching; hence blanched endive is less poisonous than it would be if eaten in its natural state. It would be curious

to know if this had anything to do with the process as a branch of culture. The *lactucarium* brought into notice some years ago by Dr Duncan of Edinburgh, who found it could be administered where poppy opium could not with safety, was prepared from the juice of lettuce.

The native country of the lettuce is unknown; it, however, appears to have been cultivated in Britain since 1562. According to Herodotus, it was in use 550 years before Christ; yet Pliny says the ancient Romans knew but one sort. In his time they were cultivated so as to be had at all seasons of the year, and even blanched to render them more tender. Gerard is the earliest English author who writes of them. He gives an account of eight sorts cultivated in his day. It is quite evident, from the names of many of our still cultivated sorts, that they must have reached us from the Greek islands—Cos, for example—and from various places in the Levant. Italy, Egypt, and the south of France have contributed their share.

*Uses.*—As one of our best salad herbs, the lettuce is well known—eaten raw in French salads, with cream, oil, vinegar, salt, hard-boiled eggs, &c. It is also eaten by many with moist sugar and vinegar, and some prefer it with vinegar alone.

It is excellent when stewed, either alone or eaten with partridge; and in most vegetable soups it forms an ingredient, and is an excellent addition to Scotch broth and hodge-podge, as a substitute for cabbage. It is eaten at almost all meals by the French; by the English after dinner, if not served as adjuncts to dishes during the repast; and by many after supper, the time when the Romans first ate them—but in the time of Domitian they changed this order, and served them with their first entries at their feasts, much as is done in many parts of the Continent at this day. In a raw state lettuce is emollient, cooling, and in some degree laxative and aperient, easy of digestion, but containing little nourishment.

*Propagation.*—The only mode of propagation is by seed.

*Sowing and planting.*—As lettuce is required throughout the whole year, sowings must be made from the beginning of February to the end of September—say twice in February and March, and three times each other month. But where young lettuce is required when about 2 inches high, the seed will require to be sown once a-fortnight during winter, and once a-week during summer and autumn. The hardy kinds, to stand over winter for early spring use, should be sown in August and September. The first crop sown in February should be upon a slight hot-bed, and when about 2 inches high should be transferred to a colder bed covered with glass, and protected from frost. These may, in the beginning of April, be trans-

planted to the bottom of a wall having a southern exposure, where they will be protected by the projecting coping, and by the awnings used to protect the blossoms of the trees. In default of such, plant in the warmest border the place affords, and protect by branches or other means most at hand. These may be set at 6 or 8 inches apart, and the smaller taken up with balls, and planted in the open border about the beginning of May, setting them 12 inches apart each way, as the smaller and hardier sorts should be chosen for this purpose. In February and March, seed should be sown on a warm border, and the plants protected until fit for planting in the more exposed borders or quarters of the garden. For a first general summer crop, sow about the end of March and beginning, middle, and end of April, in a well-exposed place, and continue sowing as above. During the heat of summer, sow on borders with a north aspect, and keep the ground moist by watering. Lettuce is much improved by careful transplanting; therefore every crop, as soon as the young plants will handle, should be set in nursery-beds sufficiently thin as not to touch each other. For this it is impossible to give exact dimensions, as so much depends on the varieties sown—the cos or upright-growing kinds requiring less space than the cabbage sorts; and even in each of these there exists a considerable difference in size. In all cases of nursery-bed transplanting, there is no error in planting thin, as the thinner the plants are the stockier they get, and the better rooted—the purposes aimed at in this stage of their growth. The beds prepared for them should be in high cultivation—that is, thoroughly enriched and completely pulverised. If a little half-decayed turfy soil, or half-decayed leaves, were dug into such beds, the roots would work into them, and lift with better balls, and especially so by using the transplanting trowel, fig. 27.

In removing them from the seed-bed to the nursery plantation, the ground should be well watered if dry. Instead of pulling up the tender plants, as is usually done, the ground should be loosened by the transplanting fork, fig. 55, which is a useful implement, and may be employed in taking up root-weeds too firmly fixed in the soil to be drawn up by the hand. Its principal use, however, is in loosening the soil

about the roots of young seedling plants, such as cabbage, endive, lettuces, or the like, previous to their removal to the nursery-bed, and also in

Fig. 55.

TRANSPLANTING FORK.

facilitating their removal from it to the place of final planting, when the transplanters, figs. 29, &c. are *not* to be used, or the transplanting trowels, figs. 27 and 28. The use of all the latter implements is to remove with compact balls of earth around the roots; and they are of great service when plants of a large size are to be removed, particularly during dry weather, and when the least possible check is to be given to their growth. A saving of time and space is obtained by their use: for example, most of the Brassicæ, the lettuce, and endive, may be retained in nursery-beds, even should the former attain a height of 9 or 10 inches, and the two latter 4 or 5, and until the ground intended for them shall be cleared of its present crop. The fork, fig. 55, is, on the other hand, to be employed for lifting young crops of onions, leeks, lettuce, endive, and similar long and tender-rooted plants, so that, by loosening the soil around them, they may with greater safety be taken up than if pulled by the hand. These forks are of various sizes—the smallest is 3½ inches broad at the points of the prongs, 5 inches in length of prongs, and 10½ inches, including the handle. The prongs are flattened, and are half an inch broad at the broadest part, tapering to a sharp point. The fork is attached to the handle by a bent neck, the part of which that is attached to the prongs acts as a fulcrum, while the handle acts as a lever.

Fig. 56 is a modification of the last, the prongs of which are 6 inches in length, and which,

Fig. 56.

TRANSPLANTING FORK.

with the bending at the neck and handle, measures 13 inches in length. In this case the prongs are round, tapering to a point, are three in number, and form a fork 3 inches in breadth. It is used for similar purposes as the last, and also as a planting tool.

When transferred from the nursery-beds to the open quarters after the beginning of May, shallow drills should be drawn according to their size, and the plants set in them: being somewhat below the general surface, they will derive shelter; and should water be required, which will be the case in dry weather, it can be more advantageously applied. If in plan-

tations by themselves, they should be accommodated according to their natural full size. Such sorts as the tennis-ball, or the *Laitue grotte*, two of the smaller sorts, will have plenty of room if 10 inches apart; while such as the drum-head will require nearly double. It is seldom, however, unless in large gardens, that plantations of lettuces are made to any extent by themselves; they form a sort of element in mixed planting, and therefore are often interlined with other crops, such as cauliflower, cabbage, broccoli, &c., in which case a lettuce plant is very properly placed between each two of the others in the same line, that no interruption may take place in stirring the ground between the rows. In such places they are usually cut for use before they injure the regular crop.

The London market-garden practice is to sow the white cos variety from the 10th to the middle of October in frames, which are filled with soil to within 6 inches of the top, giving a slope of 1 foot in 4 the length of the lights, which always face the north. As soon as the seeds are sown the sashes are removed, and a man is placed in this department to keep off the sparrows, give air, and shut up in case of rain, the great secret being to keep them as dry as possible, and to let them have all the air they can get. This will appear strange to a non-eating salad reader, but it should be remembered that millions of this variety are so grown within a few miles of London, and the price obtained pays the expense. They are planted out in February or early in March, in rich well-trenched ground (after celery), 1 foot apart each way. Mr Cuthill, on whose high authority the above statement is made, observes, that "gentlemen's gardeners buy the same seed, but, owing to their mismanagement during winter, and the poor state of the ground, they cannot grow such fine lettuces as the market-gardener. Some of the latter," he continues, "are too greedy in regard to crops—for instance, they have often three crops on the ground, all coming forward one after another: but the best cultivators do not do this; it tramples the ground, and does not give any crop fair play. The rapid growth of a lettuce depends much upon hoeing or stirring the soil."

About the beginning of October an abundant supply of the hardier varieties should be planted out at the bottoms of garden-walls, on dry warm borders, and on raised banks, sloping both towards the sun and also *from it*. On these, in open places, lettuces often stand the winter well; and should those on the southern side be cut off by strong sunshine succeeding severe frosts, those on the opposite side may escape, as the process of thawing will take place more gradually on them. In cold and elevated situations, pits and frames will be required to insure their safety. In such circumstances the plants should be kept moderately dry, and as much exposed to the light and air as possible: hence the lights should be kept off during good weather; and when on, should be tilted up both night and day, to admit full ventilation. If in frames, it will be of advantage in this respect if they be clear of the ground the thickness of a brick, so that air may pass freely through; in very severe weather they may be let close down to the ground. Covering the spaces between the plants with coal-ashes will be found of advantage.

In planting lettuce to stand over winter at the bottom of walls, every aspect should be made use of; for it is often found that those set behind a north wall will succeed better than those having the protection of a south one.

Besides planting at the bottoms of walls for protection during winter, wherever there are pits or frames and glasses to spare for the purpose, these should in like manner be filled with young lettuce-plants, to afford a spring supply should the others fail.

The seed of lettuces is small and light; half an ounce will sow a bed of 80 square feet, and will, under ordinary circumstances, produce eight hundred plants. The seed being small, it is necessary the ground should be well pulverised and made smooth before it is sown, and that it be not covered more than about the eighth of an inch.

Some recommend sowing lettuce on the ground where it is to remain, either broadcast or in rows, and, when the plants come up, to thin them to the distance of from 6 to 14 inches apart, according to their size or sort. This is a waste of

ground; for while they are in the seed-bed or nursery plantation, they are progressing in growth, while other crops may be ripening off to make way for them. Besides, the process of transplanting greatly lessens their disposition to run to seed.

*Subsequent cultivation.*—During spring the young crops must be protected from frost, and during summer from drought by copious waterings of manure-water, and frequent stirring of the ground between the plants; and snails and slugs should be kept under by watering with lime-water when the ground is dry, or dusting with lime in powder when it is already too moist. During winter the plants should be kept dry, clear of weeds, dead leaves, and all matter likely to encourage damp amongst them. The ground should be frequently stirred amongst the plants, and abundance of air given to those under glass frames or hand-glasses. In the growing season every stimulant should be applied, for much of the excellence of the crop depends on its quickness of growth. Blanching being often desirable, the cos varieties will be hastened towards maturity by having their leaves loosely tied together with strands of matting: the cabbage sorts do not require this attention. For means of preserving during winter, see *ENDIVE*; the means and method of proceeding are alike in both.

*Forcing.*—The lettuce is seldom forced in Britain; on the Continent there is a slight stimulus given to produce them fine during winter and early spring. In Holland and Belgium this is carried on with great care and success. The means adopted will be understood by what follows.

The Dutch and Belgian mode of obtaining fine lettuce throughout the winter is—About the beginning of October, not later, an exhausted hot-bed, on which melons or cucumbers have been grown, or, in default of this, a bed of fresh materials well fermented, and in which the excess of fermentation has ceased, is chosen, and fermed into a bed for the purpose. These beds, we may observe, are for the most part either wholly or in part under the ground surface, a pit being dug out for their reception: this is rendered necessary from the intensity of their winters. After the heat has considerably declined, the surface is earthed over to the depth of a foot or more with light soil, chiefly

decomposed leaf-mould with an admixture of sand, and filled up to within 9 inches of the under surface of the glass. The surface is rendered smooth and level by slightly beating it down with the back of a spade, and is then most correctly marked out into squares corresponding exactly with the size of the square of glass, and immediately under them. The plants, being previously sown very thin three weeks or a month before, are not excited by any extra means; on the contrary, they are kept exposed, and so become sturdy, stocky plants, so that when they have formed their fourth leaf they are judged fit for being transplanted into the prepared bed. One plant only is placed in each square, and that in its very centre. A few plants are put along the back and ends of the bed to serve as substitutes should any of the principal ones be eaten by the wireworm, which is very troublesome; if not required, these are thrown away. We do not recollect seeing any of the cos varieties so grown, but the cabbage kinds only: the Klein groen, or small green with black seed, very similar to our tennis-ball, or the Laitue grotte of the French, is used where the squares of glass are small; and the Groote geel or large white, similar to our drumhead or Silesian, where the squares exceed a square foot each. After planting a slight watering is given, and the whole surface of the bed is neatly covered with white sand, which is kept during the whole growth exceedingly clean and free of weeds and muscous matter. The lights are then put on, and made to fit exceedingly close all round the sides and ends of the frames, these being rebated for their reception; and no air is given for the first two or three days—that is, until the plants have taken root. Afterwards air is admitted, but with extreme caution, the lights being slightly elevated both at bottom and top, so that a complete change of air takes place almost instantaneously: this is found better in practice than a less efficient and more protracted mode of ventilation, and perhaps on this a great deal of their rapid growth and delicate crispness depends. In the early part of winter this ventilation is often left on during the day and night also; but the sashes are never completely removed, but kept on to keep the surface and the plants dry. When the lettuces have attained their full size, and have become completely cabbaged, air is totally withdrawn; should the leaves touch the glass, the frame is carefully elevated a few inches to prevent their coming in contact with it, and running the chance of being injured by frost. When the frosty nights come on, the utmost vigilance is exercised to prevent the frost passing through the glass, for if it did so, the whole crop would inevitably perish: covering must therefore be attended to, as the exclusion of cold and damp are the principles of their preservation. During the whole process, no artificial heat must be applied; and water must also be withheld, as it is probable that the roots, having passed through, or nearly through, the bed of soil, abstract sufficient moisture from the dung-bed below, thus rendering surface-watering unnecessary. To do

justice to the Belgian, German, and Dutch gardeners, we must say that their lettuce so grown is equal at Christmas to what we usually see in our own gardens in July and August. It should, however, be observed that with them a frame or two of such lettuce is considered as great a triumph of skill as a house full of four-pound queen pine-apples is with their brethren in Britain. To keep up a winter supply, two or three sowings are made, and consequently the same number of plantings. At this season frames are not required, as with us, for wintering planting-out plants, and other requirements in English practice, therefore every frame and glass sash at the command of the Continental gardener is employed in the production of his lettuce crops. The same practice has been repeatedly tried in England—as at Longleat, Bulstrode Park—but with very varied success. The late Mr Nieman, a celebrated Dutch gardener, brought over by the late Mr Labouchere, often acknowledged to us the great difficulty he had to contend with in the cloudy atmosphere at Hylands in Essex, even when compared with that of Holland. It is probable, however, that the more variable state of our climate had its share in his difficulties. A remark of this excellent cultivator is worth recording in this place—namely, that the difference even of two days in plantations made in October not unfrequently caused a difference of from a month to six weeks of their attaining maturity towards spring. The plants are kept as close to the glass as is possible without their touching it, and the reason for placing each plant exactly under the centre of a pane of glass is to prevent the chance of drip falling into its heart, which would utterly destroy it. For this purpose, also, the glass should be kept in the best possible repair, and the laps should be leaded or otherwise secured.

*Taking the crop.*—As lettuce is gathered for use, the whole plant should be pulled up by the roots; but as there would be a great chance of the earth, particularly from amongst the fibres, getting in amongst the leaves in their transit to the vegetable-house, it is better to cut the roots off and bury them in the ground in which they grew. The outer leaves should be cut off, and the root part of the stem cut clear over with a sharp knife, the whole plant carefully washed and rinsed in clean water, after having been steeped a few minutes in the salt-water tun; any of the tips of the leaves injured by frost in winter, or by insects or drought in summer, should be carefully cut off, and the utmost vigilance exercised that aphides and other insects are not allowed to remain attached to the leaves, and that all sandy and earthy particles be carefully washed out; the lettuce should then be set on end, the

top undermost, in a clean salad-basket, to allow the water to drain completely out; and it should be understood that it, as well as all other salads, receive no further cleansing after they are sent from the garden.

*Approved sorts, and their qualities.*—Lettuce is divided into two very distinct tribes or sub-families—namely, the Cos and the Cabbage kinds. The former are of upright growth, bardy, and in general firm and crisp; the latter less hardy, and more soft and flaccid, and even on that account preferred by some. The same difference exists in regard to their merits for cooking, some preferring the one and some the other. French cooks usually choose the cabbage kinds.

*Green Paris cos.*—This is the best variety of cos lettuce at present grown, and although less hardy than the brown cos, it withstands our ordinary winters when planted at the bottom of walls. As a spring, summer, and autumnal lettuce, we think it unrivalled, growing to a large size, of a fine green colour, and, from the manner in which the outer leaves cove over the interior ones, becoming nicely blanched without having to be tied together. It is known as Sutton's superb green cos, Ady's fine large cos, and Kensington cos. It is the Romaine verte Maraichère, and Chicon, ou Romaine verte Maraichère, of the "Bon Jardinier."

*Paris white cos.*—This is the sort most generally grown by the London market-gardeners, millions of it being produced annually within a few miles of London alone. Next to the green Paris cos this is the largest, the best, and the longest in running to seed of all the summer lettuces we have grown. It is less hardy than either the last or the following, and with them may be considered all of this class required in any ordinary garden. This opinion is, we observe, confirmed by Mr Thoupson in the sixth volume of "The Journal of the Horticultural Society," p. 26, who remarks, "It was sown April 10th, and had not commenced to run July 27th, while all the other cos lettuces sown on the same day were showing flower." Known also as London white cos, Sutton's superb white cos. It is the Romaine blonde Maraichère of the "Bon Jardinier," and is much cultivated, as well as the last, around Paris. Seeds white. The common white cos runs to seed sooner than this variety.

*Brown cos.*—This old and excellent sort still maintains its position as being the hardiest of all the class. It grows to a large size, blanches well, and is exceedingly crisp and tender. It is known as Bath cos, brown Bath cos, white-seeded brown cos, Wood's improved Bath cos, hardy brown cos, and Sutton's Berkshire brown cos. This excellent variety is not much cultivated on the Continent; the outside leaves being of a brownish colour renders it with them objectionable. Seeds white.

*Waite's white cos.*—An excellent variety, apparently intermediate between the Paris green cos and Paris white cos; not quite so dark or green as the former, yet somewhat greener than the

latter. The three varieties are so excellent that either or all may be grown advantageously.

*Bath green cos.*—Has great merit as a hardy winter green sort, and nearly related to the old Bath cos, only less brown on the outer leaves, and while it has white seed this has black seed. Hence we have, in seed catalogues, black-seeded Bath cos and white-seeded Bath cos: the latter appears to be the hardiest, while the former seems to be the best.

*Artichoke-leaved lettuce.*—Comparatively a new variety of singular habit, having the leaves long, upright, and very much cut at the edges; it is a hardy variety, blanches well, and does not speedily run to seed. It is the *Romaine à feuilles d'artichaut* of the "Bon Jardinier." The seeds are black, and should be sown in June and July for autumn and winter use.

The above may be considered the very best, and the following rank next to them in this respect: new crystal cos; early green cos, which is identical with the Brighton green cos; Brighton cos; Egyptian cos, and Egyptian green cos; golden cos, the same as the Florence cos; Alphonse cos (of this variety the French cultivate two sub-varieties, the one having black and the other white seed); red-spotted cos, the same as Aleppo, bloody, and the Sanguine ou panachée, *Romaine panachée à grain blanche*, of the French. Seeds white. Seed-lists contain such names as Bearfield cos, Victoria cos, white Brunoy (the latter said to be very large), and a variety of other names, which are either unknown to us, or which are identical with some of the above.

Of cabbage lettuce we have for summer cultivation—

*The Neapolitan.*—A large, white, crisp, and firm variety of great excellence—we think the best of all others for summer use, as it comes in early, and is long in running to seed, blanching itself naturally; leaves somewhat curled, toothed at the edges. Seeds white.

*Large white.*—Heads large, flat, compact, with smooth leaves and white seeds. Of medium earliness, and not inclined to run to seed during hot weather. A profitable sort. Known as the late cabbage, large mogul, Swedish or sugar, Saxony, and princess, and is the *Royal à graine blanche*, *Blonde Paresseuse*, *Blonde d'été* ou *Jaune d'été* of the French.

*Malta.*—Heads compact and flattish; leaves palish green; blanching naturally; of a fine pure white colour and tender consistency. An old tried variety. It is the *Laitue de Malte* of the "Bon Jardinier."

*Versailles.*—Not much removed from the Neapolitan; the leaves are, however, of a paler green, of excellent quality, and cabbaging white and crisp. It is the *Laitue de Versailles*, *Laitue de Versailles blonde*, of the "Bon Jardinier."

*Imperial.*—An excellent large sort, but inferior to either of the above. It is known as the union, and is the *Imperiale* ou *grosse Alemande* of the French, and differs only from their *Laitue Turque*, or *Turque à graine noire*, in having white instead of black seed.

*Black-seeded yellow.*—Very similar to the large white cabbage lettuce, differing chiefly in

the seeds of the present one being black. It is the *Blonde de Berlin*, *Blonde à graine noire*, *Royal à graine noire*, of the French.

*White Silesian.*—One of the largest size. Leaves crumpled or wavy at their edges; palish green, slightly tinged with reddish brown on their outer surfaces. It is known as the drum-head, large drum-head, or cabbage, Spanish, imperial. A long-cultivated sort. It is the *Batavia blonde* ou *Silesie* of the "Bon Jardinier."

Of other summer cabbage lettuces the following rank next to the above: *Asiatic*, *Belle bonne*, *Ice*, *Grand admirable*, *Victoria*, *Mogul*, (which is identical with *superfine new French*), *Laitue de Hollande*, *Grosse brune paresseuse*, and *Grosse grise*. The *Nonpareil* of the English is synonymous with the *Metrelle* of the French.

Of cabbage lettuce we have, for winter and early spring use—

*Tennis-ball.*—A long-cultivated sort. Heads small, firm, white, and crisp; very hardy, and not apt to run to seed in spring. Very much prized with French cooks, who dress it whole in a variety of ways. This is one of the sorts which should be sown about the 12th or 15th of August. The seed is black. It is known also as *green ball* or *button*, and *capuchin*. It requires little room in frames during winter, and yields a great return in spring, as almost the whole plant is eatable.

*Black-seeded grotte.*—An excellent winter lettuce, somewhat similar to the last. There is a black and white seeded variety, and also various other grotte lettuces, much more cultivated in France than with us, all of great merit. Where small, hard, compact, and delicate sorts are required, this class should be extensively grown; not that they differ much in appearance or quality, but by procuring several sorts by name, the chance of disappointment in procuring some that are good is lessened.

*Brown Dutch.*—An excellent hardy free-growing sort, attaining a pretty large size, cabbaging freely, and of good quality. The outside leaves are reddish brown, the centre ones white and delicate. It is less hardy than the others in this class; but as it is of much larger size, its cultivation is of consequence.

*Hardy-green Hammersmith.*—An excellent small hardy green variety, which has long been in cultivation. Leaves much wrinkled and concave; dark green in colour, and thicker than most of this class; seeds white; the hardiest sort in cultivation. It is known also as the early frame, early dwarf Dutch, Roman cabbage, hardy green, green Dutch, and Prussian cabbage. It is the *Laitue verte* of Continental gardens.

*White Dutch.*—Leaves yellowish green, sometimes tinged with reddish purple at their tips; seeds white; cabbages freely, and of excellent quality; somewhat larger than the tennis-ball. Known also as the early yellow, early green forcing, and early cabbage. It is the *Laitue à bord rouge*, ou *Cordon rouge*, of the French.

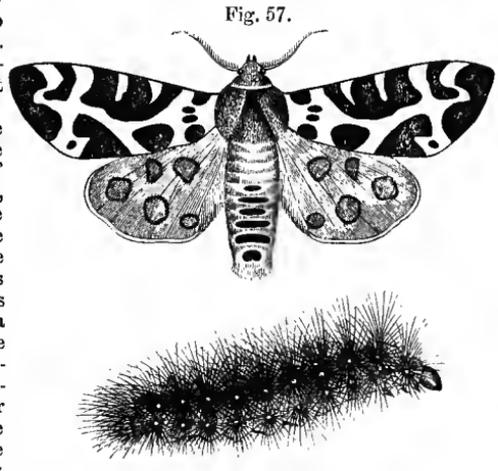

There are four species of *Lactuca* cultivated besides *L. sativa*, the presumed type of the cultivated varieties described above. These are *Lactuca crispata*, *palmata*, *intybeca*, and *quercina*.

Their merits have, however, attracted little attention in Britain. The French profess to have several kinds in the seed-shops, which they consider adapted to the purpose of growing to be cut young, as we do mustard and cress. These they call *Laitue chicorée*, *Laitue à couper*, *Laitue épinard*. Any sort of the upright or *cos* varieties will do equally well.

*Diseases and insects.*—Among the latter are the lettuce-fly (*Anthomyia lactuæ* Bouch.), the larvæ of which, according to Ruricola, in "Gardeners' Chronicle," make their appearance in August, but more abundantly in September. They are not very readily distinguished from those of the cabbage and turnip, being of a yellowish-white colour, tapering towards the head, which is pointed, and armed with two short black claws at the nose. These maggots live in the involucria of different varieties of lettuce, feeding upon the seed and receptacle; and when they have devoured these, they push themselves out backwards, either to enter another seed-vessel, or fall to the ground to become pupæ. When the seed stems are gathered and dying, the larvæ change to pupæ, being bright chestnut coloured; oval cases, which are rough when examined under a lens, with two minute tubercles at the head, and two hooks and a few other tubercles at the tail. In May a few of the pupæ hatch, although they are sometimes found as early as April and as late as July. The male fly is intense black, clothed with short hairs and bristles; the eyes reddish brown, and meeting above; face inclining to chestnut colour, with a bright spot of the same on the crown; the fore part of the trunk bears four varying whitish stripes; the body is ashy grey; the segments blackish, at the base a deep black; wings, two, stained with black and beautifully iridescent; the base and poisers ochreous; the nervures of the wings pitchy. The female is entirely ashy grey, and less bristly; the eyes not meeting on the crown, with a bright chestnut-coloured stripe between them; body oval; the apex cone-shaped; horns and legs blackish; wings and nervures lighter than in the male, which it equals in size.

The *Arctia caja*—*Euprepia caja* of others—fig. 57 (the garden tiger-moth), appears in July, and often commits sad havoc upon lettuce crops, and also on strawberries. The caterpillar is one of the most voracious of all its class, eating double its own weight per day. They do not eat the solid part of the leaf, but suck out the juice, and thereby destroy the plant as completely as others do who devour the leaves and stems. It has been ascertained that one of these caterpillars, weighing 36 grains, voided daily more than 15 grains' weight of excrement; yet its own weight only increased 2 grains daily. The caterpillar of this moth is to be found in June, and the perfect insect in July, so that its period of voracity is providentially not of long duration. It is well known in gardens in its perfect state, and may be readily captured while on wing by using an entomologist's net. Hind wings bright red, with blue-black spots; fore legs of a reddish brown, marked with creamy white; thorax brown, with a red neck-band; abdomen red, with blue-black bars. The caterpillars are

dark brown, thickly covered with reddish-brown hairs. They cast their skin quite entire, and

TIGER MOTH AND CATERPILLAR.

these may be frequently picked up in mistake for the living insect.

Another enemy to the lettuce, as well as many of the products of the garden, is the *Tipula maculosa* of Hoffmannsegg (the spotted garden-gnat),

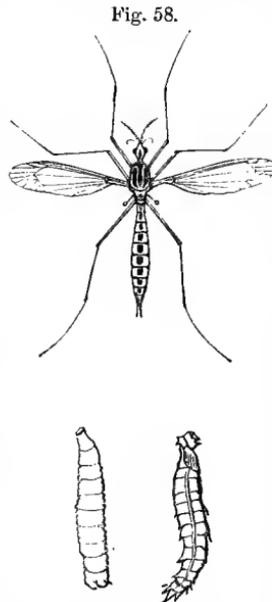

Fig. 58.

SPOTTED GARDEN-GNAT OR CRANE-FLY, GRUB, AND PUPA.

fig. 58. The grubs of the genus *Tipula* are amongst the worst enemies to gardens. It would appear that, until lately, we had no correct idea of the number of species by which we are infested—*Tipula oleracea* apparently bearing the whole blame of the injury done us by his family. Ruricola, in "Gardeners' Chronicle," 1846, p. 317, appears to have drawn attention to this species, and describes them as follows: "These larvæ are of the same dirty earth colour as those of *T. oleracea*"; but they are only three-fourths of

an inch long, and as thick as a large crow-quill. They are wrinkled, and when at rest contract themselves, drawing in the head and thoracic segments, so that this portion looks more like the anal extremity: the animal, however, is able to thrust out its head and crawl along very

well, although it is destitute of feet. The head is small, brown, and furnished with two black jaws, short antennæ, and, I believe, minute palpi. Two vessels of a pale colour are visible down each side of the back, and one in the centre; the tail is furnished with two divaricating hooks, and two short teeth between them; the stern being truncated, which will readily distinguish the larva from that of *T. oleracea*; it has two large spiracles, with two tubercles below, and two fleshy masses, which are capable of great dilatation, and assist it exceedingly in walking. In the spring these larvæ change to pupæ in the earth. They are about the same length as the larvæ, but scarcely so stout, and of the like dirty colour; the head and thorax are defined, the latter having a short slender horn projecting on each side; the wings are small, but distinctly visible, as well as the legs, which are placed between them. There is a spiny elevated line on each side of the abdomen; each segment having a transverse row of minute spines above, and five larger ones beneath; the penultimate joint is surrounded by six longer spines and two smaller ones; and the apex produces a large conical process above, and a shorter one beneath. The flies are abundant in May and June in meadows, gardens, fields, hedges, and especially on the sea-coast. There must be either two or three broods in the year, or a constant succession of the flies, although the spring may be the season when the greatest number are hatched; but that will vary with the temperature." The gnat is "not quite half an inch long, but the wings expand one inch. The male is of a fine yellow colour; the black horns are longer than the thorax, and taper; they are 13-jointed; the first joint is elongated, the second small and cup-shaped; all the others are elliptical, with a few bristles at the base of each, excepting the apical one, which is very minute; head with a large black patch on the crown; forehead conical, with a little black dot on each side; the face forming a cylindrical rostrum, with a hairy beak, bearing a black spot on the top. Palpi are longish and black; the eyes are hemispherical and black, but there are no ocelli; the thorax is marked with three black stripes down the back, the centre one the shortest, and the sides are spotted with black; the scutellum has a black dorsal stripe; the abdomen is linear and obtuse, with a row of black spots down the back, and smaller brown ones on the sides; the wings divaricate or rest horizontally on the body; they are of a smoky, yellow tint; the costa is yellow; there are an areolet, two little stigmatic cells, and seven apical ones; six long black legs, very slender and tapering; base of thigh pale yellow, and of shanks yellowish brown. The female is rather larger; the horns shorter; the abdomen is fusiform; the apex acuminate, and furnished with two fine sharp lateral valves, and a smaller central one. The eggs, which are scattered by the female, are intensely black, but dull, oval, and spoon-shaped. This, however, might arise in my specimens from their not being fertile.

"Some idea may be formed, from the following data, of the mischief committed by this insect.

On the 23d of April I found the grubs at the root of my pease; on the 29th some had eaten off trusses of flowers in the strawberry beds, close to the crown, retiring afterwards just beneath the surface of the earth; the first week in May they were not uncommon among the roots of lilacs and under tufts of grass; on the 28th of the same month I observed some recently transplanted lettuce drooping, and, on examination, found the roots separated from the crown, a little below the surface, and close to where these grubs are difficult to detect, owing to their colour, and their remaining quite motionless when disturbed. The end of July they were eating the roots of dahlias, carnations, and various flowers; and the 7th of August they infested some potato ground along with the *T. oleracea*; after which I lost sight of them.

"Lime-water will not kill them; and the only mode I have been able to adopt with any success has been to search round sickly plants, and dig up all that have been killed by them, and destroy the culprits; but this must be done speedily, otherwise they will soon decamp to feed upon other plants. I should think watering with brine, nitrate of soda, or perhaps strong liquid manure, would keep them from our crops."

Brine applied sufficiently strong to kill or drive away these grubs would kill the plants themselves. Sulphur, tobacco or quassia water, or spirits of tar incorporated with the soil, we think, would be found more effectual. Besides these, a species of aphid has recently been discovered which commits great depredations on lettuce crops, by attacking the roots of the plants. This species does not appear to have been observed by entomologists prior to 1849, and hence remains unnamed.

Birds are fond of the seeds of lettuce, therefore newly-sown crops should be protected by netting the beds over; and the seed, while ripening, requires a similar protection.

*General remarks.*—Select some of the best-formed plants that have stood over winter; thin them out where they stand, if the place is eligible; if not, transplant them in spring to a warm and sunny spot, setting them from 2 to 3 feet apart, according to the size of the kinds. Keep no two sorts near to each other; or, better, as the seed retains its vegetative properties for many years, grow in small gardens, only one sort for seed in one season. The seed will be ripe in August. Cut the plants when the flowers have faded, and leave them on a dry border for a day or two; the seeds will mature themselves in the seed-vessels, deriving nourishment from the sap in the plants; when dry, remove them under cover of a dry airy shed, and thrash out the seed when it begins to fall out. The seed ripens very irregularly if left standing, the top parts ripening and shedding before the lower parts and the side shoots are equally matured.

#### § 4.—ENDIVE.

*Natural history.*—Endive (*Cichorium endivia* L.) belongs to the natural order Compositæ, sub-order Cichoracæ, and tribe Cinchoræ, and

to the class Syngenesia and order *Æqualis* in the Linnæan arrangement. For derivation, *vide* **Succory**. It is said to be a native of the East Indies, China, and Japan, and to have been introduced in 1548. This Phillips disputes, and we think with good reason, for Ovid mentions it in his tale of "Philemon and Baucis." Columella also notices this vegetable as sufficiently common in his day; and Pliny tells us clearly that it was "eaten both as a pot-herb and salad by the Romans in his time;" and in book xx. chap. 8, he speaks of the endive or garden succory as being medicinal. Gerard gives an account "of the manner by which the garden endive was preserved for winter use in the time of Queen Elizabeth." His method may not be uninteresting to the horticulturist of the present day. He says—"Endive being sown in July, it remaineth till winter, at which time it is taken up by the roots, and laid in the sun or air for the space of two hours; then will the leaves be tough, and easily endure to be wrapped up in a heap, and buried in the ground with the roots uppermost, where no earth can get within it, which, if it did, would cause rottenness; and which, so covered, may be taken up at any time convenient, and used as salads all winter, as in London and all other places is to be seen; and then it is called white endive." Taking a hint from this quotation, we have often, in taking up endive in November, planted it in an inverted position, by burying the leaves in dry peat earth (which is an excellent antiseptic), the roots uppermost, and exposed to the air, and have kept it in good condition from two to three months. From all we can learn, we are disposed to believe endive a native of Egypt, and that it was carried from thence to Italy, and from thence to Britain, along with many other of our horticultural productions.

*Uses*.—The leaves are the only parts used, and these only when blanched, to diminish the natural bitterness of taste. It is one of our best autumn, winter, and spring salads, and is also stewed much in the same way as lettuce.

*Propagation*.—In a cultivated state it can only be regarded as an annual, and is therefore propagated by seed, which is light, and vegetates freely: half an ounce of seed will sow a seed-bed of 40 square feet.

*Sowing and planting*.—The earliest crop should be sown in May, on a warm border, in rich and well-pulverised soil. In sowing, scatter the seed thinly, and cover to the depth of a quarter of an inch. If sown earlier, the plants are apt to run to seed in autumn; and if sown too thick, they come up slender, and if not timeously thinned, are much retarded in their growth. For principal crops, sow twice in June and twice in July; and for a late crop to stand over winter, if mild, and to come in early in spring, sow again towards the middle or end of August.

The seeds may be sown broadcast in beds 3 feet in breadth. In dry warm weather water freely, both while in the seed-bed and nursery plantation. As bulk of vegetable and tenderness in texture, as in the case of the lettuce, are the great requisites, every stimulus should be given to increase the rapidity of growth, and this will be accelerated by the application of liquid manure, such as dissolved guano, soot, or pigeons' dung, applying it either early in the morning or late in the afternoon. When the plants are about 2½ inches high, remove them carefully, and transplant them into another bed of equally enriched soil. Set the plants from 3 to 4 inches apart each way, water at planting, and afterwards, if the weather is dry. From this bed they may be transferred, when about 4 to 5 inches in height, to where they are to come to their full size. The early crop should be sparingly planted, unless the demand is great, as they are very apt to shoot up to seed, more especially if the seed is of last year's growth. A part of this early crop may be planted on a warm well-exposed border, and the remainder interlined with newly-planted-out broccoli or cabbage, or between rows of dwarf pease, the partial shade being of advantage to them, and in some degree preventing their running to seed prematurely. In taking up for final transplanting, great care should be taken that the roots are disturbed as little as possible, and that as much soil as will conveniently remain about them be also taken along with them—and for this purpose the planting trowel should be used, instead of the dibber. As the plants are taken up, set them closely together in the planting-tray, with their leaves upright, and on no account follow the barbarous practice of cutting the leaves off nearly by the middle. The planting-tray is a light shallow box, about 27 inches in length, 18 inches wide, and 3½ inches in depth. In the sides should be cut two slits sufficient to introduce the fingers, for greater convenience in carrying it to the place of planting. Such trays are much better than baskets, as they prevent the loose earth falling on the walks, protect the roots better from the air during their transport, and are more economical, on account of their greater durability. The ground for the principal crops should

be open and well exposed to the sun, thoroughly manured, and dug or trenched to the depth of 2 feet. Draw drills from 12 to 15 inches apart, according to the kind of endive to be planted, as some, like the Batavian or broad-leaved sorts, require more room than the green-curled, and those to be used early in autumn may also be set closer together than such as are to remain till a later period. The drills should be 3 inches deep, which, by the earth falling into them during the process of hoeing, &c., will assist in blanching the crop; they also render the process of watering more convenient, and economise the fluid, and afford, as in all cases of drilled crops, greater facility for cleaning the ground and stirring it up, upon which so much of the success of all crops depends. The plants, according to size, as stated above, should be planted with the trowel, at from 9 to 14 inches apart in the row: if the ground is in proper condition, this will not be found too great a distance; if otherwise, a less distance will suffice.

In all cold and late situations, the warmest spot in the garden should be set apart for this crop, as it is, with the exception of the kidney-bean and potato, the most tender of all our ordinary esculents. The shade of trees should be avoided; and for the latest crops of all, a dry place, and if possible sloping to the south, should be chosen.

*Subsequent cultivation.*—The summer crop will require nothing more than attention to watering, and keeping the ground clear of weeds, until it has nearly attained its full size, when a portion of the crop should be blanched; but this should not be done all at once, only in progression—say from 20 to 50 plants about every third day. The methods of blanching are various. The Belgians, who are the best growers of this crop in the world, commence at the end of a row, and, taking the leaves carefully up with both hands first, hold them tight with the left hand, and with the right hand apply a small willow twig, and frequently a leaf of *Juncus glaucus*, which they use largely for all temporary tying purposes, round the leaves at top, thus causing the large outer leaves to blanch the more tender ones towards the heart of the plant. They are methodical in all their gardening opera-

tions; and so, in this case, they thus tie up as many plants as will last for six days, at the end of which time they begin to gather the crop, which will be beginning to blanch, and will every day be improving. They take up as many as they require for the day's consumption, and with the twigs or rushes now disengaged, they proceed to where they left off tying at first, and tie up as many more as they have that day taken for use; and in this way they go on throughout the whole crop. They also sometimes draw a little earth about the plants as we do, but they prefer the former practice.

The English practice, in market-gardens, is to tie up in the same way, using strands of matting instead of twigs or rushes, performing the operation once in eight or ten days. This operation should in all cases be attended to in dry days, or when the leaves are completely free of damp from rain or dew. In private gardens the same plan is followed, though, in some cases, they draw earth around the plants when both are in a dry state, and thus effect the end, although not so completely. Indeed, when the earthing-up system is to be followed, it will be found expedient to tie up the leaves first, and therefore, if this is done properly, earthing up must be superfluous. By tying up the plants while quite dry, drawing the leaves up in a conical form, and tying them tight about 3 inches under their tips, damp is prevented from getting to the hearts, and no deterioration can take place in the flavour; and therefore, we would say, for summer crops, this is the better way. For autumnal supply, when the weather is less favourable, and every means should be employed to prevent

decay taking place, in consequence of damp, in private gardens at least, the endive blanching-pot, fig. 59, should be used. These are merely modifications of the sea-kale blanching-pot, fig. 39, diminished in size; and as there is no occasion for a portable top or lid to enable the cultivator to examine his crop, they are made

Fig. 59.

ENDIVE BLANCHING-POT.

all in one piece, having a knob at top to serve as a handle for lifting them off or on. They are from 9 to 12 inches in diameter, and the same in height; are placed over the plants when nearly full grown, the leaves being gathered up with one hand, while with the other the pot is placed over them, so as to enclose them completely, and thus insure their blanching, while they are protected from frost, snow, or rain. The curled-leaved varieties are much more readily blanched than the broad-leaved or Batavian sorts, therefore a corresponding degree of care is required in performing the process. As to the length of time required for blanching, much depends on the season. During summer, while the plants are growing vigorously, the process will be effected in a week; while towards autumn, and during winter, when vegetation is more sluggish, double or treble that time will be required. The other means employed are to invert empty flowerpots over the plants, taking care to stop up the holes in their bottoms, laying a slate or pan-tile over each plant, particularly the green curled sorts: the Batavian, from its difference in habit, does not admit of this process. Setting two long narrow boards along each side of the row, and bringing them together at top in form of a triangle, and afterwards drawing earth over them to keep them steady; covering the dwarf-growing sorts with half-decayed leaves, dry tanners' bark, sand (a method in use in the days of Gerard), coal-ashes, or even sawdust, are all had recourse to; but all of these, as will readily be seen, are far inferior to using the blanching-pot, or even the tying-up process.

For protection during winter, the London market-gardeners take up their latest crops, and set them thickly on sloping banks, by the sides of hedges, for the sake of shelter; while others throw up long narrow ridges, in an east and west direction, and plant both sides, which produces a succession—those on the southern side coming in first, while those on the opposite side, if later in arriving at perfection, have often the advantage over the others of withstanding the winter's cold better, being less influenced by the freezing during night, and rapid thawing during the day.

Partial shelter may be afforded the plants during winter, when planted in the

open garden, by sticking the ground between and around them with old peastakes, branches of trees, firze or broom branches. This wards off cutting winds, and catches the perpendicular frost as it falls; but, in using such means, they should be stuck firmly in the ground, to prevent their being blown about so as to injure the plants by friction; neither should they be above 2 feet in height, as the lower they are the less effect the wind has upon them.

The best way, however, to secure fine endive during winter, is to take the full-grown plants up in November, or before severe frosts set in, choosing a dry day, and when the leaves are also dry. Tie the leaves loosely together with matting, first removing a few of the largest and oldest outside leaves; take them up with good balls of earth attached to them, and carry them to the conservative-pit (fig. 676, vol. i.), or the span-roofed vegetable-pit (fig. 677, vol. i.), and plant them in moderately dry sand, in half-decayed peat earth, if it can be procured, which, on account of its antiseptic properties, will resist decay longer. They should be placed closely together, but not so close as to touch each other. In the one case, they will be kept perfectly dry, in consequence of the permanency of the roof, while ample ventilation is secured by opening the sides, as shown in our figure. In such a structure they will enjoy almost as much air as if in the open ground, while they will be completely protected from damp and frost. The conservative-pit (fig. 676, vol. i.) offers also an excellent means of keeping endive, and all similar plants, if taken up with balls, and planted in it. The boarded roofing, which is in convenient pieces, keeps the interior dry, while light and air, when wanted, can be fully admitted, by propping it up as shown in our figure. All places for the purpose of keeping esculent vegetables during winter, should be placed in a dry airy situation, and with a northern aspect, so that the sun may rarely shine upon them: during their season of hibernal existence, every stimulus to growth should be guarded against. We have recently constructed a very useful pit for this purpose, 150 feet in length, and 7 feet wide. It is simply a brick wall, 15 inches in height, built parallel with an existing north wall, covered

with standard or Ridder Morello cherries, the branches of which are 3 feet from the ground. A batten of wood, with notches cut out opposite the stems of the trees, is fastened to the wall by holdfasts at that height; to this, and to the wooden wall-plate on top of front wall, the rafters are fixed, at the distance of  $3\frac{1}{2}$  feet, which is the breadth of a great portion of our glass lights and felt shutters, that either may be employed if necessary. For protecting lettuce and endive the former are not required; and the latter, during winter, are mostly in use for covering over the glass lights of pits, &c. during the night. As a covering for this pit, we employ the boarding used as portable coping to the garden-walls (*vide* fig. 40, vol. i.), which during winter is not required: these are laid upon the rafters in an imbricated manner, but not fixed to them, but they are secured to each other by cords every 6 feet, after the manner of Venetian blinds; but instead of drawing up, like them, they are folded up the one over the other, when air is wished to be admitted, or when it is necessary to open them to take out the supply, remove dead leaves, &c. When the plants are fully grown they are removed from the quarter, tied up, and planted in rotten tan within the pit; the boarding is put on, and the whole safely secured. We have never had so fine a supply of endive before as we have this season, and we are still cutting, on the 10th of March, that which was put in the first week in November.

*Soil and manure.*—The object being to produce the largest amount of vegetable matter, and in the shortest space of time, it follows that the soil cannot be too rich or in too high a state of cultivation for this crop. Beyond the application of stable-yard manure, as usually applied, we use no other manure, save that at every watering we enrich the liquid by the addition of guano, soot, or pigeons' dung, and occasionally ammoniacal liquor, or the water through which gas passes during the process of purification, which appears to be an excellent manure for most garden crops, but cannot everywhere be procured. It should, however, be understood that this liquor is not gas-tar, which of itself would have very opposite effects.

*Taking the crop, and subsequent preservation.*—Endive is always used in a blanched

state, both for appearance sake and to get rid of a certain natural bitterness contained in the green leaves. It is divested of its outer, coarser, and unblanched leaves and roots, with any points of the remaining leaves that may have been injured, or have begun to decay. It is then thoroughly washed, rinsed afterwards in clear water, or in salt and water, allowed to drip dry, and placed in a clean basket fit for use. The preservation of the crop being so connected with its subsequent culture, for that the reader is referred to the last paragraph.

*Forcing.*—Endive is rarely forced in Britain, our chief dependence being placed on the preservation of the preceding year's growth over winter. The truth is, with all our affectation for French cookery and salad-eating, we are a vast stride behind our neighbours on the other side of the Channel in both. They force endive, and we do not. Their mode of proceeding is thus given in the "Bon Jardinier," which contains all that is new in French gardening: "For early-forced scarole (broad-leaved or Batavian endive) the seed is sown in January, under glass, in a strong heat. After the seeds have vegetated, and the plants are fit to handle, which will, in general, be from twelve to eighteen days after sowing, they are pricked out on another hot-bed, at a lower temperature than the last, ventilation is attended to, and in course of the end of February and during March the crop is ready for use. The plants, of course, are small compared to those grown by us in the open air, but they are produced in great number on account of the extent of framing every garden contains, and the abundance of stable-yard manure procurable, by which almost all the forcing in the market-gardens about Paris is carried on. When the scarole has attained the height of 6 or 8 inches in the frames, it is tied up to blanch, which it does in a few days. Sometimes they sow the seed in October, in a bed with a mild bottom-heat, and afterwards prick out the plants into a similar bed, placing them at the distance of about 6 inches asunder, either under glazed sashes supported on frames, or under *cloches* or large bell-glasses, placed close together on the heated material. These they cover in severe weather with *paillissons* or straw mats, which they very

properly prefer to Russian mats, the most indifferent of all protections, warding off neither cold nor wet in so efficient a manner. We have a third mode, by sowing about the middle of September in a cold frame: in about three weeks the plants are of fit size to prick out under glass to gain strength, after which they are transferred to a glass frame, set pretty thickly together, and protected from cold by ample coverings alone." It will be understood that these crops are not intended to attain the same size they do with us, but are cut for use while quite young and tender; and by such means we might obtain a better supply of young lettuce for winter use than we do by growing them in boxes, pots, or pans, in the high temperature usually done. This mode, however, imposes a great amount of labour in covering and uncovering; and from the high price of labour with us compared with that of France, it would hardly pay the commercial grower. In some few private gardens, such supplies, both of lettuce and endive, are kept up; but, in general, the demand for glass is so great with us for other purposes that few private families would afford the necessary means. Winter salad-growing is the *beau idéal* of the French gardener; his mind is, as it were, concentrated on it, and indeed he has little else to think of. Not so with those of Britain, whose winter operations are far more multifarious, besides the difference of climate.

*Approved sorts and their qualities.*—The endive, like the lettuce, is divided into two very distinct classes—the Batavian or broad-leaved (the Scaroles of the French, the Breitblattrige-endive of the Germans), and the curled-leaved (the Chicorée of the French, the Endivien-cichorie of the Germans.) An excellent paper was published some years ago, in the 4th vol. of the "Transactions of the Horticultural Society of London," on the varieties of endives. The French seed-lists contain many names; those of Britain contain few, and of those, three or four are all that is in general inquired for.

The *broad-leaved Batavian* and *small Batavian* are the only two broad-leaved sorts worth the attention of the general cultivator. The former is known also as broad-leaved endive, common yellow, and double yellow; the latter is the Scarole petite, Scarole courte, Scarole ronde of the French. The former is that most usually grown, but from careless seed-saving is not always to be procured genuine. The latter has the following merits, which are worth notice, and are thus given by Mr Thompson, from spe-

cimens grown in the London Horticultural Society's garden: "Leaves pale green, broad, of moderate length, slightly ragged at the edges; inner leaves hooked at the top, naturally forming a good heart; blanching with little trouble, and is mild and sweet compared with many others." Nearly allied to the broad-leaved, but inferior to it, is the curled Batavian, fine-curved and yellow-curved Batavian, which are all the same.

The *large Batavian* is merely a large variety of the small Batavian, inferior to it in not hearting so well. It is the Scarole grande, Scarole de Hollande, of the French.

*Lettuce-leaved Batavian.*—More tender than the other varieties, therefore not adapted for winter crops or cold localities, unless for early summer use; the leaves are large, blunt, and cut at the edges: it does not blanch without tying up. It is known as the white Batavian and new Batavian, and is the Scarole à feuille de laitue, Scarole blonde, of the French. The green and white Batavians are only seed-list names, referable to the common broad-leaved sort.

*Large green curled.*—An excellent sort, differing from the following only in being somewhat larger in size, and in having its outer leaves more upright. It is known as the green curled, yellow winter endive.

*Small green curled.*—With the last, the two best of their class, and most extensively grown. Leaves about 6 or 7 inches long, beautifully curled, the outer leaves lying close to the ground, the inner ones thickly set, forming a compact heart, easily blanched, very hardy, and, with the last, best adapted for winter use. It is the Chicorée frisée, Chicorée de Meaux, Chicorée endive, of the French.

*White curled.*—This sort is much used by the French for cutting young, as described in paragraph *Forcing*. The full-grown leaves are nearly 8 inches long, and when grown in the open air they seldom or ever form a heart, and are besides tough and bitter. It is the Chicorée blanche, Chicorée toujours blanche, of the French. Certainly not worth cultivating for a general crop.

*Small French green curled.*—This sort is much cultivated in France for the earliest crop, hearting early, and being less liable to run to seed than some others. It is so small and so prostrate that it is difficult to tie up. It is known as the fine-curved, and is the Chicorée fine d'été, Chicorée frisée fine d'Italie, and Chicorée d'été, of the French.

*Dutch green curled.*—So near in all respects to the large green curled as not to be worth growing as a separate sort. Like the other, it is hardy, and blanches well.

*Long Italian green curled,* or *Endivia longa.*—Similar, if not inferior, to the following.

*Italian green curled,* or *Endivia riccia.*—So similar to the last as not to be worth cultivating as a distinct sort; indeed, neither is worth cultivation in a climate like ours.

*Triple-curved moss.*—A curious new sort, exceedingly well curled, and, although a variety of the following, is worth cultivating to a limited

extent. It is the Chicorée mousse of the French.

*Staghorn endive*.—A variety of no long standing; leaves upright, much cut and jagged at their points, which accounts for the name. It hearts well, but is very tender, running to seed too soon, and being impatient of wet and cold. Useful as a summer endive, but useless for winter crops.

*Insects and diseases*.—Endive is pretty well exempt from both, but, like most tender esculents, is often attacked by slugs (*Limax*) and snails (*Helix*); but these can readily be subdued by dusting over with powdered lime, or watering with lime-water. Several species of the genus *Iulus*, or snake millepedes, attack the roots of endive. We have lately discovered *Iulus pulchellus*, fig. 48, *I. terrestris*, and *I. complinatus*, abundant about the roots of endive plants in a cold pit. In the quarters where they grew, hundreds have been dug up during November and December, notwithstanding the plants were repeatedly watered with lime and soot water during their growth; and even nitrate of soda was pretty profusely applied at the time of digging the ground. In some seasons, however, lime and soot water have been found to save the plants; and a single experiment made this last season seems to argue in favour of flowers of sulphur being sown in the drills previous to the plants being planted out; and this, no doubt, would have acted better had the sulphur been buried deeper.

*General remarks*.—The seeds of endive are saved in the same way as those of chicory and lettuce (*which see*). The European names are Chicorée des Jardins in French; Endivia in Italian; and in German and Dutch the same; Endibia in Spanish.

## § 5.—SUCCORY.

*Natural history*.—Succory, chicory, or wild endive (*Cichorium intybus* L.), belongs to the natural order Compositæ, sub-order Cichoraceæ, and tribe Cichorææ, and to the class Syngenesia, and order Æqualis. The generic name is of Egyptian origin, adopted by the Greeks. The plant has been used by the Egyptians from the earliest ages, and it is most probable that they would communicate to the Greeks its name, as well as the manner of using it. Forskahl says the Egyptian name was Chikouryeh. They did, and still do, make their chicory of much consequence; and it is well known that it, along with similar plants, constitutes half the food of the Egyptian peasantry at this very day. The specific name *intybus* is derived from the Arabic name Hendibeh; and Pliny informs us that in his day they called the wild endive (our chicory) Cichorium, and the cultivated sort (our endive) they call Seris. According to Phillips, the garden endive was cultivated in England in the reign of Edward VI.; “but the wild endive or succory,” he adds, “*intybus*, being indigenous to the soil, was grown in all probability at a much earlier period, both as a pot herb and as a salad;” and Gerard informs us that “the leaves of these wild herbs are boiled in pottage, or

broths, for sick and feeble persons;” and this generally correct authority adds that the wild endives (our chicory) “do grow wild in sundry places in England, upon wild and untilled barren ground, especially in chalk and stony places.” There can be therefore no doubt that, cultivated or uncultivated, the chicory was in his day, 1548, sufficiently well known.

The chicory is indigenous to many parts of the south of England, particularly in chalky soils, and it has been long cultivated in Italy, France, and other parts of the Continent as an agricultural plant, the leaves being used as green food for cattle, and the roots, when kiln-dried and ground, as a substitute for coffee. It has also been long used in these countries as a salad herb, the leaves and roots both being used; “yet in this country,” says London, “it had not attracted the notice of horticulturists till after the time of Miller.” A revival of its uses was no doubt brought to England, from the Continent, after the general peace in 1814–15.

*Use*.—In other countries, as we have stated above, it has been extensively and profitably grown, particularly in Holland and Flanders, and has occupied a place in gardens for an unknown length of time, the leaves being blanched, and used as one of their most popular winter salads. The blanched leaves are called Barbe de Capucin, or Friar's beard. In Belgium the roots are scraped and boiled, and eaten along with potatoes, or with a sauce of butter and vinegar. The roots have been taken on board ship, and planted in boxes filled with sand, and in this way afforded wholesome salads for months together. Its principal use is as a substitute for endive, and it is employed for the same purposes.

*The mode of propagation* is by sowing the seed. A quarter of a pound will be sufficient for an ordinary private garden, as it is light, somewhat like endive, to which it is closely related.

*Sowing and planting*.—The seeds are sown, towards the end of June, in rich deeply-trenched ground. Sow thin, and cover about one quarter of an inch. When the plants come up, thin them to the distance of 6 or 7 inches apart, transplanting those thinned out into another piece of ground equally manured and trenched, to allow the long fusiform roots to extend deep into it. Some sow, after the Flemish manner, in the broadcast way, and transplant on the same system. The drill mode is, however, better in both cases: the drills should be 9 inches apart, and the plants 6 inches distant in the row; for the stronger the plants are, and the more room the foliage has for development, the more elaborated matter will be thrown into the roots; and it is this prepared matter, stored up in them during their

growing season, that will supply the means for the young coming leaves during winter forcing, for they of themselves can collect little or nothing towards the support of the crop.

*Subsequent culture.*—About the beginning of October the roots should be lifted, the leaves being carefully cut off, but not so close to the crown as to endanger the hearts of the plants. Amateurs had better leave 3 inches of the base of the old leaves, to prevent accident. The roots are then planted as thick as they can well be done in a bed of sand on the floor of a mushroom-house, packing the sand closely about them, and, when finished, giving a good soaking of tepid water. Old boxes may be filled with them, and casks, as is usual on board of ship, having their sides perforated with holes  $1\frac{1}{2}$  inches in diameter, and 7 or 8 inches apart. Lay a few inches of sand in the bottom of the cask, and on that lay the roots horizontally, with their crowns in the centre of the holes; on this layer of roots lay more sand and roots until the cask is filled, watering each layer of roots as they are covered with the sand. Large flower-pots may also be used, or indeed anything that will keep the sand together. It may be convenient to fill many of these at once; and by placing them in a dry cellar or open cool shed, they will remain for a month or two stationary. For the first gathering, one or more of these should be removed to a warmer place, where a temperature of from  $45^{\circ}$ ,  $50^{\circ}$ , to  $60^{\circ}$  can be maintained, and where light can be completely excluded. In a week afterwards place another supply in, and so on during winter, or as long as the stock of roots lasts. They will seldom afford more than one gathering, and may be then thrown away, and the boxes or casks filled again with roots from the open ground. In this way a constant succession of salad may be kept up from the beginning or middle of November till April. Some recommend taking up all the crop of roots at once: this is unnecessary, until the beginning of February, when they will begin to become naturally excited into growth. It is expedient then to remove them to a bin of sand in the cellar, or to bury them deep in the ground, to prevent their growth. It is also recommended by some to shorten the roots and remove the side fibres; but this is only cutting off the resources of the

plant, and lessening its means of producing a crop of large succulent leaves.

This excellent and wholesome salad was, we believe, first brought into notice in Covent Garden market by the indefatigable Mr Cuthill, who, in 1839-40, carried the first sample of it which appeared there in his own hand. It was in consequence of a letter from that individual, published in "The Gardeners' Magazine," about fifteen years ago, that this plant was first grown as an article of field-culture, for the purpose of its roots being used for mixing with coffee. This is somewhat strange, seeing that it has been a common marketable article on the Continent time out of mind.

Mr Cuthill sows his chicory about the first of June, either broadcast or in drills. When the plants are up, they are thinned out to a foot apart, and the ground is kept free from weeds. The roots are taken up in November, and stored by exactly like beet. When endive becomes scarce, the chicory roots are planted in 16-sized pots, five roots in each. When the chicory begins to spring, invert 24-sized pots over those the roots are in; exclude the air, and place them in a forcing house or frame: each pot will afford three or four cuttings. A dark mushroom-house, where a fire is kept, is an excellent place for chicory; and a cellar is good for spring crops, but seldom warm enough, if not artificially heated, to depend upon for a regular winter supply.

The Belgians and Dutch blanch immense quantities of chicory during winter and spring; indeed, it forms one of the most prominent articles in their vegetable markets for several months together. The roots are taken up in autumn, and all the larger ones selected; they are then placed in a bed, almost as close as they can stand together, with merely a little earth to fill up the spaces between them, experience having taught the Belgian gardener the important fact pointed out theoretically by Mr T. A. Knight, that the new annual supply of leaves of plants of this description is derived from the stock of sap elaborated in the preceding year, and requires nothing from the soil but moisture. Upon the bed of roots thus closely packed together, and defended from frost in winter, a slight hot-bed of manure is laid in spring, with 6 or 8 inches of earth interposed. Into this earth the leaves shoot, struggling

for light and air, and becoming perfectly blanched and crisp, and losing most of their natural bitterness. With us who have greater convenience in the shape of heated cellars, or other places capable of having light completely shut out, we manage better, by planting the roots in beds on the floor, and thus produce the crop at less risk and greater certainty as to time, without half the labour. Planting in large pots or in boxes, and inverting pots or boxes of the same size over them, and setting them on the floor of a vinery, and behind the hot-water pipes or flues where they exist, or indeed in any out-of-the-way place where there is a temperature from 50° to 55°, and exclusion from light, will secure this excellent winter and spring salad in great perfection, and with little trouble.

Those who desire it during spring may readily blanch it in the open ground, leaving some roots where they grew, and placing sea-kale or endive pots over them. They will continue to yield a crop until they begin to run to seed.

*Taking the crop.*—Each head of leaves is cut when of 7 or 8 inches long, taking with them a thin slice of the crown to keep them together, as in cutting sea-kale. When washed and tied up into small bundles of a handful each, they are fit for dressing. Three handfuls will make a good-sized salad, and may be eaten alone with oil and vinegar, or mixed with a little chervil and tarragon, or with young lettuce.

*Sorts and their qualities.*—The Continental growers profess to have three sorts—the common large-leaved, the Chicorée à navet, or Café-chicorée, and the variegated.

*General remarks.*—The European names are, Chicorée sauvage in French; Cichoria in Italian; Gemeine cichorie in German; Suikerei in Dutch; Achicoria in Spanish. In saving seed, select some of the strongest roots that have not been forced; support the flower-stalk as it advances, and cut them over when flowering is done, and treat them as recommended for lettuce. The seed will keep three or four years.

## § 6.—DANDELION, TARRAGON, ETC.

*Dandelion* (*Leontodon Taraxacum* L.) belongs to the natural order Compositæ, sub-order Cichoracæ, and tribe Taraxacæ, and to the class Syngenesia and order Æqualis in the Linnæan arrangement. The generic name is derived from *Leon*, lion, *Odon*, a tooth, from the tooth-like divisions of the leaves. Indigenous to most parts of Britain, particularly in rich soils.

The young leaves, even in their green state, make an excellent ingredient in salads; and the leaves are an excellent substitute for succory, and for this purpose they are blanched during winter in a similar manner. (See Succory.) It is a neglected and despised plant, which might be made much use of by the poor, and those living in towns who have no gardens; for roots of it may be got for the digging up, and, if planted in sand in a dark cellar, or even in pots set on the window-sill, much wholesome matter might be obtained from it. The roots are as valuable as the leaves. It is produced in great quantities in the London markets, although we are not aware of its cultivation being tried upon a commensurate scale to meet the demand.

The amateur who may wish to grow the dandelion in his cellar for salad purposes, should possess the root-extractor, fig. 60, an excellent implement for the purpose of taking up such

Fig. 60.

ROOT-EXTRACTOR.

roots, which can be carried in the pocket. The mode of using it is to thrust it deeply into the ground, so placed that the root may be taken between the prongs. The bent part near the handle, acting as a fulcrum against the surface of the ground, greatly facilitates the withdrawal of the root without breaking it, when the handle is pressed towards the ground.

*General remarks.*—The European names are, Dents de lion, or Pisse-en-lit, in French; Amargon in Spanish; Paardebloem in Dutch; Lowenzahn in German; Piscia in letto in Italian. Our own common English name bears a close resemblance to some of these.

*Tarragon* (*Artemisia Dracunculus* L.) belongs to the natural order Compositæ, sub-order Anthemideæ, and to the class Syngenesia and order Superflua in the Linnæan arrangement. The generic name is derived from *Artemis*, one of the names of Diana. Pliny, however, informs us that in his time there was an opinion that the plant was named after Artemisia, the queen of Mausolus, king of Caria. The specific name is said to have been given from the tortuous form of the roots resembling the sinuous tail of a dragon; others think it derived from Tarchon, the Arabic name of the plant. It is a native of the south of Europe, others say of Siberia, and was introduced into England in or before 1548.

It is cultivated for its leaves and the points of its young shoots, both of which are used as an ingredient in salads, soups, stews, pickles, and other compounds. Tarragon vinegar, so much esteemed as a fish-sauce, is made by infusion of the leaves in common vinegar. It is also added to most salads to correct their coldness. Three or four plants are sufficient for an ordinary family; but if required during winter in a forced

state, twenty or more plants will be required. A very small portion is sufficient for a day's consumption, either for salads or soups, a small handful of the leaves or young shoots being quite sufficient. When used with salads, it should be cut up very small, and served on a plate by itself, so that every guest may season his salad to his own taste, as many have a dislike to its flavour.

Being a hardy perennial, it is increased by dividing the roots; every portion, however small, will grow, if only a bud be left at the top. It may also be propagated by seed, but this is seldom done.

The seed may be sown in March. The slips or roots should be planted at the same time, or in autumn. It may also be propagated by cuttings of the young shoots, taken off in July, when the plant is in full growth, and these will strike freely under a hand-glass in a shaded situation. It should be planted in a dry warm soil, as it is apt, when planted in cold damp soils, to die during winter.

If seed is sown, it should be in a small seed-bed broadcast, and the plants removed, after they have attained the height of 6 inches, into rows in an open part of the garden, free of shade and damp, and where the soil is perfectly dry, in lines a foot and a half apart, and the plants a foot asunder in the lines. They will speedily increase, and become fine bushy plants the same year.

Their subsequent cultivation consists in keeping the ground around them clear of weeds; and when the plants are showing flower-stems, they should be cut off, unless a plant or two be left for seed. This is, however, seldom done, as the plant propagates sooner and better by dividing the root. Towards November, take up a few of the plants, and plant them in large flower-pots or boxes, to be placed in a mild heat to produce green leaves and shoots during the winter.

The plants potted in November may be from time to time, to suit the demand, placed on the floor of a vinery, or in a moderately-heated pit, in any temperature from 45° to 60°.

A very small portion of the green leaves or tops of the young shoots should be picked off, and served with the salad daily; a somewhat larger quantity when it is to be used for stews or soups, and in still larger quantity when to be pickled, or for making tarragon vinegar; and for the latter purposes it should be supplied when the plants are at their fullest size.

*General remarks.*—No insects that we are aware of attack this plant. It should be planted in very dry soil, and in a sunny situation. The European names are, L'Estragon in French; Dragencello in Italian; Dragun in German. A quarter of an ounce of seed will be sufficient for most gardens, but young plants are usually purchased from the nurseryman. Two dozen will be enough to make a plantation.

*Burnet* (*Poterium Sanguisorba* L.) belongs to the natural order Rosaceæ, and to the class Monœcia and order Polyandria in the Linnæan arrangement. The generic name is derived from *Poterion*, a cup, because it is used in cooling drinks.

Indigenous to Britain; generally found in calcareous soils which have long been under pasture.

The young leaves are often used in mixed salads, particularly when made in the Italian style, which, according to an old proverb, is good for nothing without them. The branches and leaves are also used in soups. It was formerly in higher repute than at present.

*Propagation.*—By seeds sown in March or in September, in any common garden-soil. Half an ounce of seed will be sufficient for any garden. It does not propagate so freely by division of the plant; and although this is recommended in books, it will be found better to transplant the young seedlings, when 3 inches in height, into lines a foot apart, and the plants 9 inches asunder in the line. A plantation thus made will last from six to ten years.

*Subsequent cultivation.*—All that is required is to keep the ground clear of weeds, to prevent the plants running to seed, by cutting over the flower-stalks as they appear. A few plants should be cut over by the ground occasionally, to keep up a succession of young and tender leaves. Twelve plants will be sufficient for an ordinary family. A small handful will be sufficient for a salad; for soups, double that quantity will be required.

The European names are—Pimperella in German; Pimprenella in French; Pimpinella in Italian.

## § 7.—WHITE AND BLACK MUSTARD.

The *white mustard* (*Sinapis alba* L.) belongs to the natural order Cruciferae, and to the class Tetradynamia and order Siliquosa in the Linnæan arrangement. The name is derived from *Sino*, to hurt, *Ops*, the eye—as its pungency hurts the eyes; by others, from the Celtic *Nap*, applied to the cabbage tribe. It is indigenous to many parts of Britain—found growing in corn-fields. It was formerly called *Senovia* in English. Tusser mentions the use of mustard in Queen Mary's time; but it is uncertain whether it was the white or the black mustard he meant. Gerard informs us that the garden-mustard, which produces the whitest seed, was not become common in Elizabeth's reign, but that he had distributed the seed into different parts of England to make it known. Mustard was not manufactured in his day, but was brought to table whole, or bruised in vinegar.

The principal use of both white and black mustard in gardens is as an indispensable ingredient in salads, the young leaves and stalks being cut close to the ground before the formation of the second series or rough leaves appear. Formerly the dry seed was pounded with vinegar, and, according to Gerard, "is an excellent sauce—good to be eaten with any gross meats, either fish or flesh, because it promotes digestion and sharpens the appetite."⁵

Propagation always by seed. From a pint to ten quarts of seed will be annually required, according to the demand. Where a daily supply is required, seed should be sown every third, fourth, or fifth day throughout the year. As the crop is to be cut when in the cotyledon leaf

state, it should be sown thick; and, to prevent the earthy particles mixing with the leaves, it should never, if possible, be covered. Cotyledons, or seed-lobes, are appendages of the embryo, enclosing or accompanying the tender plantlet, and containing its first nutriment. Upon the principle of the presence or absence of cotyledons we have the grand and primary division of plants that are cotyledonous on the one hand, and plants that are acotyledonous on the other; as well as the subordinate divisions of monocotyledonous, dicotyledonous, and polycotyledonous plants also. These distinctions are deemed to be the true key to a natural system, and form the basis of the arrangements of Jussieu. The two first lobe-locking appendages, vulgarly called seed-leaves, as shown in this plant, exemplify the cotyledon. The London market-garden method is to sow the seed thickly on the surface of old tan made smooth and level, and laid over the floors of their vineries; for to such an extent is this branch of culture carried for the supply of the metropolitan demand, that one grower alone, Mr Chapman of Vauxhall, sows a whole house every other day. The tan is well wetted previous to sowing the seed, and no covering whatever is put on the seed beyond a damp mat, which is laid over to keep in the moisture. They vegetate according to the degree of temperature kept up, which should, however, not exceed 60° or 65°. When the plants are about 2 inches high, the mats are removed during the day to admit light to give the necessary green colour to the young leaves, but are put on again at night to hasten the growth; for, as with all salads, the quicker the growth the better and more tender the produce. The crop is cut when from 4 to 5 inches in height, and each handful, as it is cut, is put into a clean punnet-basket, and is fit for use. If thus grown, no washing is required, excepting a slight rinse shortly before using. Steeping such salads in water, to rid them of sand and dust, destroys the flavour, and renders them flaccid and tough. They should be cut as soon previous to use as possible. The above may be called the winter culture upon a large scale. For private use, shallow boxes or pans are used, and these are placed in any spare corner of hot-houses or pits, where the necessary temperature is kept up. The boxes should be 4 inches deep, and of a length and breadth suitable to the accommodation; and sowings should take place every third or fourth day, and the crop placed as near the glass as convenient, on suspended shelves or otherwise.

Summer culture must be conducted on the same principle, in spring and autumn covering the crop with hand-glasses; and, during the heat of summer, sowing on cool borders behind a wall.

To save seed—a process scarcely worth the attention of the private grower, on account of its cheapness—a crop may be sown thin in an open part of the garden in March or April. The seed will ripen in August, and, when thoroughly dried, may be thrashed out for storing by. The European names are—*Moutarde* in French; *Mostazo* in Spanish; *Senapa* in Italian; *Senf* in German; and *Mosterd* in Dutch.

*Black mustard* (*Sinapis nigra* L.) belongs to the same class and order as the last, and is, like it, a native of Britain, and found in similar situations; it is also a native of Italy. It is no doubt the mustard of the ancients, although there are great doubts of its being the mustard of Scripture, whose seed is referred to by our Saviour. It is by some cultivated as a salad plant, the same as the last, but the tender leaves are oftener used during spring as a substitute for, or as an addition to, spring greens. The uses of its seeds for medicinal and domestic purposes are well known. The ancients ate the young plants stewed, and the leaves of the older plants were boiled like other pot-herbs. The young leaves of both this and the white mustard are usually mixed with those of cress in salads. When grown as a spring green, the seed is sown in autumn, and the plants are thinned out to a foot or 18 inches each way. Like all oleiferous seeds, they greatly exhaust the ground, and retain their vegetative properties for an unknown length of time; so that, where it has once been grown, and the seed allowed to drop and become buried, they will come up for a century or more afterwards. This is the reason why charlock (*Sinapis arvensis*) is so difficult to eradicate out of land it has once been allowed to seed on. The black mustard has been recommended to be sown on soil infested with wireworm, the roots being so acrid that the larvæ will not eat it, and hence perish from hunger. The European names are the same as for white mustard.

## § 8.—CRESESSES.

*Garden cress* (*Lepidium sativum* L.) belongs to the same class and orders as the last. The generic name is derived from *Lepis*, a scale, from the scaly form of its silicles, or parts of the pods to which the seed is attached. Its native country is unknown. Introduced to England before 1548.

Of the same use as the white mustard (*which see*). Of the white mustard there is only one variety—of the garden cress there are several, all, however, used for the same purposes; but, being somewhat different in their cultivation, we shall notice them under the next head, viz.—

*The common garden or plain-leaved cress*, and the *curled-leaved*, are the two sorts most generally cultivated, and in this respect they differ not from that of the white mustard already detailed. In respect to merits, the former is the most delicate, as it is used younger; but the latter is preferable, particularly for garnishing.

*Golden cress*.—A variety of slower growth, and of a yellowish-green colour. Seldom grown.

*Broad-leaved cress*.—A coarser variety, with broad spatulate leaves, seldom forced, but usually grown for mixing along with rue, leek-tops, nettle-tops, and overgrown mustard, in rearing young turkeys and other poultry. For soups it answers very well.

*Normandy curled cress*.—A very valuable variety, by far too little cultivated. It was introduced to England about 1814, and in vol. vii., p. 38, of the "Gardeners' Magazine," we brought it before the notice of the public. Our

practice, to secure a constant supply from the open air, as it is much harder than any of the other varieties, is to sow at the bottom of a south wall in September and October; for Scotland, read beginning of September and middle of October. This will, with very slight protection during severe frosts, afford a supply during winter and spring. Sowings made in an open border in March and April, and in a rather cool shaded place in May, produce crops in regular succession. In gathering it for use, the younger leaves should be *picked off* singly, rejecting the older and larger; but on no account cut the plants over as is done with common curled cress, as the Normandy variety will continue sending up fresh leaves for a long period. It is difficult to procure the seed true, the common curled being in general substituted for it. If, therefore, one is fortunate enough to obtain it genuine, it is better to save the seed for future use.

*Broad-leaved Normandy.*—A sub-variety of the last, with broader and more succulent leaves. Its culture is the same as the last. To have either of these in perfection, they should be thinned out to 9 inches or a foot apart.

*General remarks.*—The European names are—Cresson Aenois in French; Tuinkers in Dutch; Mastinco in Portuguese; Gemenie garden kresse in German; Crescione in Italian; and Mastuerzo in Spanish.

*Water cress (Nasturtium officinale H. K.)* belongs to the same class and order as the former. The name is derived from *Nasus*, nose; *Tortus*, tormented—from the effects of most of the genera upon the muscles of the nose—a name given by Pliny. Indigenous in most parts of Britain, growing in small streams, generally where the water is pure, and having a slight motion.

One of the most wholesome of all our salad herbs, and one of the oldest in use. Its qualities are warm and stimulating—the very reverse, in some respects, to most other plants used in a green or uncooked state. Xenophon strongly recommended its use to the Persians; and the Romans recommended it to be eaten with vinegar, as a remedy for those whose minds were deranged, and hence the Greek proverb—“Eat cress, and learn more wit.” The Dutch and English eat great quantities of this cress in spring, as an antiscorbutic. Gerard and Lord Bacon wrote strongly in its recommendation. The young shoots and leaves are eaten by themselves, often with bread and butter, and also used in spring soups and broths, as well as for garnishing cold meats. A salad so easily procured, and of so much importance to the health of townspeople and those of sedentary habits, cannot be too highly recommended. The supply of water-cresses brought daily to Covent Garden market alone has been calculated at 6000 bunches; and Mr Cuthill remarks that, “if 10,000 bunches more than they already received were brought every market morning, they would be all sold;” and this is perhaps not more than the half of the quantity sold in other parts of England daily.

Propagated by seed, and by planting rooted branches of the plants. Plants from seed are, however, to be preferred, as they do not run to seed so soon.

*Sowing and planting.*—Planting should be performed in spring or autumn, and sowing the seed in February, April, and June, by which fine young crops would be obtained.

Phillips recommends those having large pieces of water in their grounds to throw the plants on the surface of the water. They will mature their seed, and soon propagate an abundant supply. Cuthill says, “Few small places are without water, and nothing need be easier than to introduce it into a neatly-formed trench, 2 or 3 feet broad, and to plant the cresses,” which may be gathered in a seedling state on the margins of brooks or streams, where they naturally abound. Plant three rows along the bottom of such a trench, setting the plants 2 feet apart in the line. Cover the surface between the plants with 2 inches of clean gravel or small stones, and allow the water to flow in to cover them to the depth of 3 inches at first, increasing it to 6 inches after they have taken root and begun to grow. Very excellent instructions are given for their cultivation in the 4th vol. of the “Horticultural Society’s Transactions,” p. 540, and also in “The Gardeners’ Magazine,” vol. i. p. 151. The following is the substance of the former: The best place for forming a plantation is a clear-running stream, not more than an inch and a half deep, upon a sand or gravelly bottom; and if the water is supplied from a deep spring, so much the better, on account of the increased temperature of the water preventing it from becoming frozen during winter, and hence securing a constant supply of salad. The plants should be placed in rows parallel with the course of the stream. In shallow water, the plants should be set at the distance of 18 inches apart; in deep water, allow them from 5 to 7 feet. When the plants begin to grow in water one inch and a half deep, they soon check the current, so as to raise the water to the height of 3 inches about the plants, which is considered the most favourable circumstances they can be placed in. The cress will not grow freely in a muddy bottom, nor will the crop be so clean and well-flavoured. They should be planted in gravel or chalk. It is also absolutely necessary to have a constant current, for the plants will cease to prosper if the water is still or stagnant. They should be kept pretty thin by constant gathering, or pruning away occasionally superfluous shoots. In winter the water should be rather deeper than in summer, say 4 or 5 inches.

The beds should be cleaned out and replanted twice a-year, with a view of keeping them young and clearing away weeds, and any mud that may accumulate, as well as keeping the crop always clean and fit for use. Young plants are procured from the tops of the old ones, choosing those best furnished with roots. These are placed at the requisite distance on the bottom, with a stone on each to keep them in their places until they take root. The time of renewing the beds is in May or June, and from September to November. This renewal should be made progres-

sively, so as to keep up the constant supply. Those replanted in May are fit to cut in August, and those planted in November are ready to cut in spring. It will be expedient to place planks in such a way, a few inches above the water, as to facilitate the operations of gathering.

The young shoots, to the length of from 4 to 6 inches, should be cut (not broken) off, and then carried to the vegetable-house, and thrown for two or three hours into a tub of clean salt-water, to rid them of insects or their larvæ. They should then be rinsed in clean water, and tied up in little bunches of about half a handful each.

*Tipula repens* (Linn.), *T. sericea* (Gmelin).—The larva of this insect fixes its cocoons very firmly to the under side of the leaves of water-cresses, and in this state is unconsciously eaten by thousands. The precaution stated above, of washing them in salt water, seems to be the only way of ridding the leaves of these insects.

The European names are—Cresson de fontaine in French; Berro in Spanish; Brunnenkresse in German; Agriao in Portuguese; Waterkers in Dutch; Cressione di sorgenti in Italian. Many gardens have their water-cress beds; and no park in the kingdom, where water is to be had, even at the expense of an Artesian well, should be without one. The Parisians have formed water-cress plantations, and one or two exist in the neighbourhood of Edinburgh; and one existed a few years ago, and may do so still, at Mistley Hall, of 30 acres in extent.

*American cress*, or Belleisle cress (*Barbarea præcox* Dec.), belongs to the same class and order with the last. The name is derived from its having anciently been called the herb of St Barbara. Indigenous to Britain, and found in watery places.

The *Winter cress* (*Barbarea vulgaris* H. K.) belongs to the same genus as the last, and is also indigenous to Britain, and found in moist shady situations.

Both are used as winter and spring salads. They are reared from seed; half an ounce will sow 20 feet of drill. Sow in drills a foot apart, and an inch deep, choosing a damp shady situation. Sow about the 20th of August or 1st of September for a winter and spring supply. In Scotland a warmer and better situation should be afforded them. For summer use sow once a fortnight from March to July. Water abundantly in dry seasons.

Pick the outside leaves for use, and cut down flower-stems as they appear. In November, afford the winter-standing crop a slight shelter of small branches stuck amongst them; and if too crowded, thin out to prevent injury from damp. The seed of both is produced in abundance by leaving a few plants to come into flower during the summer.

The European names of the American cress are—Cresson d'Amerique in French; Amerikanischer kresse in German. It is also called by some English seedsmen Black American cress, and also French cress. The winter cress is known as Cresson de Terre in French; Hierba de Santa Barbara in Spanish; Winter kresse in German; Erba di Santa Barbarea in Italian; and Winterkers in Dutch.

*Indian cress*, or Narsturtium, abbreviated to Sturtion by many (*Tropæolum majus* L.), belongs to the natural order Tropæoleæ, and to the class Octandria and order Monogynia in the Linnean arrangement. This genus forms the whole of this order, which is remarkable as being the only natural order in which the peculiar acrid flavour of the Cruciferæ is found to exist. The generic name is derived from *Tropæum*, a trophy. The leaf resembles a buckler, and the flower an empty helmet, of which trophies were formed. It is a native of Peru, and was introduced to England in 1686; but the minor variety was first brought to Europe by the Spaniards in 1580. In the first edition of Gerard's "Herbal" we find it described by him as growing in his garden, where Holborn now stands. Both *T. majus* and *T. minus* are cultivated in our gardens—the former most generally. The French style the flower La grande Capuchin.

Both varieties are much cultivated as ornamental climbers; and the fruit, if gathered before it ripens, makes an agreeable pickle without the aid of spice, and is an excellent substitute for capers, which it much resembles. It is accounted a good antiscorbutic. The flowers as well as the young leaves are used in salads. The flowers are also used to garnish dishes, particularly by artificial light, and were in our early days much more employed for this purpose than at present. The seeds are pickled in salt and vinegar, when made into imitation capers.

Although both varieties are perennial in their native country, the coldness of Britain prevents their continuance through the winter; they are therefore treated as annuals, and sown every March or April. They are usually sown in single rows, one row of a few yards in length being sufficient for the culinary purposes of a private family. The seed, which is large, is deposited in drills  $2\frac{1}{2}$  inches deep. When grown for ornament, they are sown two or three seeds in a patch at the foot of a trellis or pyramidal support, and, if intermixed with sweet pea, have a very good effect. When grown by market-gardeners, or upon a large scale for their seed, they are sown in drills 3 feet apart, topped when about 2 feet in height, and treated the same as scarlet runners (*which see*). They transplant freely, and to have them early in flower, particularly in Scotland, they are sown in March in pots or boxes placed in a mild frame or pit; when 3 or 4 inches in height, they are set in a shaded sheltered place for a few days to harden off, and are then transplanted to where they are finally to grow. This is the best way to manage them, as the seed, if too early sown in cold soil, is apt to rot; and if planted out too soon, is as apt to be killed by the frost, more than 1° of which it will not stand.

*Soil*.—This should not be too rich, else a gross disposition is induced, rendering them rambling in growth, and producing fewer flowers or seeds than if on a rather poor light soil.

Neither disease nor insects seem to attack the plants. The blossoms are endowed with the power of emitting electric sparks towards evening, a phenomena first observed by the daughter of Linnæus. It is most distinctly seen

with the eye partly closed. The berries should be gathered for use while quite green. Abundance of seed will be found in a ripened state when the plants are pulled up upon the first attack of frost. They do not retain their vegetative powers above two years. Their European names are—Capucine in French; Mastruco do Peru in Portuguese; Kapuzinerblume in German; Fior cappuccino in Italian; Spaanche kers in Dutch; and Capuchinas in Spanish.

### § 9.—PURSLANE, CHERVIL, ETC.

*Purslane* (*Portulaca sativa* Haw, *P. sativa*, var. *Aurea* Haw, and *P. oleracea* L.—all the three are cultivated in our gardens) belongs to the natural order Portulacæ, and to the class Dodecandria and order Monogynia in the Linnæan arrangement. The generic name is derived from *Porto* to carry, *Lac*, milk, supposed medical quality. *P. sativa* is a native of South America, introduced in 1652; while *P. oleracea* is a native of Europe, introduced 1582.

Its young shoots and leaves, which are very fleshy or succulent, are used in summer salads, and are sometimes used in French and Italian soups, and also as pickles. Its existence is only to be looked for in gardens of the highest order.

Being annuals, they are yearly reared from seed. A quarter of an ounce will sow a bed of 32 square feet. For a first crop, sow in February or March upon a gentle hot-bed, for all the sorts are very tender, and this first crop must have the protection of a frame and glass lights. A two-light frame will be sufficient. As the plants reach the height of 2 inches, thin out to the distance of 4 inches apart; the soil should be of such light and rich consistency as that usually employed for cucumbers. The second crop should be sown upon a warm border in dry light soil in May, and successional sowings should be made, if a constant supply is demanded, every fortnight till the first week in August, after which recourse must be had to bottom-heat and the protection of glass coverings. It is best to grow them where they have been sown, but they may be transplanted in cases of emergency.

The shoots are fit for use when from 2 to 5 inches in length, and should then be cut off with a knife and slightly rinsed in clean water, when they are fit for use. The European names are—Pourpier in French; Porcellana in Italian; and Portulak in Dutch and German. The seed is not worth the trouble of saving.

*Chervil* (*Cherophyllum sativum* Pers.) belongs to the natural order Umbellifera, and to the class Pentandria and order Digynia in the Linnæan arrangement. The generic name is derived from *Chairo*, to rejoice; *Phyllon*, leaf—that is to say, a plant whose leaves have a pleasant smell. A native of several parts of Europe; by some considered indigenous to Britain.

Gerard cultivated it in his garden; and Parkinson says, "It is sown in gardens to serve as a salad herb." These are the earliest notices we have of its being cultivated in Britain. Pliny

tells us that the Syrians cultivated it as a food, and they ate it both boiled and raw. It has long been cultivated by the French and Dutch, and they have still hardly a soup or salad but the leaves of chervil make a part of the composition.

The leaves are used in most salads and in many soups, and as a seasoner it is by many preferred to parsley, when used for these purposes.

Being an annual, it is propagated by seed. To maintain a constant supply, sow about the beginning of February, and make successional sowings every month till August, about the end of which a larger sowing should be made in a warm situation, to form a winter and early spring supply. Some only sow in spring and autumn, and trust to keeping the plants from seeding; this is, however, precarious. Sow in drills 10 inches apart and 1 inch deep. Transplant only in cases of emergency, unless it be in saving seed of the fine-curved variety, which will be improved in the fullness of its leaves, if transplanted once or twice before it shoots up for seed. An ounce of seed is sufficient to sow 24 square feet. It should be sown thin. A light soil, not over-manured, is the best for all odoriferous plants.

When the leaves are 2 inches in height they are fit for gathering; a small handful is sufficient for a large salad.

*Plain chervil* is the most common, but except that it is harder than the curled varieties, it should be discarded.

*Curled chervil*.—This sort, on account of its delicately-curved leaves, is much used for garnishing, as well as for the ordinary purposes for which the plain sort is used. Being a larger grower, it requires more room for its development; indeed, the plants, to have justice, should stand a foot apart each way. When intended for winter use it should have the protection of hand-glasses, frames, or branches of trees stuck thickly around and amongst it. In very unfavourable situations it is well to pot a dozen or two plants, and shelter them under glass during winter.

*Frisized-leaved French chervil* (*Cerfeuil frise*) is an improved variety of the last, even more beautiful, but also more tender. It is best adapted for summer crops.

Few insects attack the odoriferous plants. Seeds of all the varieties are easily saved. The plants of the two last varieties should be transplanted once or twice when intended for this purpose, and a somewhat richer soil will be of advantage. The European names are—*Cerfeuil* in French; *Cerfoglio* in Italian; and *Gartenkerbel* in German and Dutch.

### § 10.—RAPE, CORN-SALAD, ETC.

*Rape* (*Brassica napus* L.) belongs to the natural order Crucifera, and to the class Tetradynamia and order Siliquosæ. For derivation of the generic name, *vide* section CABBAGE. Indigenous to Britain.

It is cut when quite young, and before the second leaves are formed, and mixed with cress

and mustard. Its culture for this purpose is the same as these. It is the Navette of the French; Mapo salvatico of the Italians; and the Rapskohl of the Germans.

*Corn-salad* (*Valerianella olitoria* Dec.) belongs to the natural order Valerianæ, and to the class Triandria monogynia in the Linnæan arrangement. The generic name is a diminutive of Valerian. Indigenous to Britain. Another species is cultivated—viz., *V. eriocarpa*, or Italian corn-salad, of much larger growth.

Both are used as a substitute for lettuce in spring. The latter sort, besides being used for salads, is also used when grown in rich soil and of considerable size, as a substitute for spinach. They are both much used on the Continent, where they appear under the names of Salade de chanoine, Mache, Poule grasse, Doucette, &c. Sow in August and September for winter and spring use, and in February and March for summer supply. The seed is small. Sow them, and cover about the eighth of an inch. An ounce of seed will be sufficient for an ordinary family.

*Brook-lime* (*Veronica Beccabunga* L.) belongs to the natural order Scrophularinæ, and class Diandria and order Monogynia in the Linnæan arrangement. The derivation of the name is doubtful. Indigenous to most parts of Britain, growing in ditches and streams often along with water-cresses, and is used for the same purposes, and cultivated in the same manner.

*Wood sorrel* (*Oxalis acetosella* L.) belongs to the natural order Oxalidæ, and to the class Decandria and order Pentagynia in the Linnæan arrangement. The generic name is derived from *Oxys*, acid—from the acid taste of the leaves. Indigenous to most parts of Britain, existing in vast quantities in moist woods. It is used as an ingredient in spring salads; and, although quite capable of cultivation, it is found so plentifully in April and May, in a natural state, as to render its culture scarcely profitable. It is much used on the Continent, and is the Oseille of the French, Acetosa of the Italians, and Sauerampfer of the Germans.

*Coriander* (*Coriandrum sativum* L.) belongs to the natural order Umbelliferæ, and to the class Pentandria and order Digynia in the Linnæan arrangement. The generic name is derived from *Koris*, a bug, from the smell of the leaves. A native of England, in corn-fields. It is chiefly cultivated in gardens on account of the tender young leaves, which are used in soups and salads. It is raised by seed sown annually—in February and March for summer use, and again in August or September for winter supply. A very few plants are sufficient for an ordinary garden.

*General remarks.*—It delights in a light sandy soil. The plants should stand 18 inches apart. European names—Koriander, German and Dutch; Coriandre in French; and Coriandro in Italian.

## § 11.—THE RADISH.

*Natural history.*—Radish (*Raphanus sativus* L.) belongs to the natural order Cruciferæ, sub-order Orthoploceæ, and tribe Raphanæ, and to the class Tetradynamia and order Siliculosæ. The generic name is derived from *Rha*, quickly; *Phainomai*, to appear, from its rapid germination. The name radish is supposed by Phillips to come from *Radix*, a root. The cultivated radish is thought to be a native of China, but it appears, by the writings of ancient naturalists, that its culture is of great antiquity in many parts of Europe, although it was not grown in England prior to 1548. They were very highly esteemed by the Greeks, and were grown largely in Egypt in the days of the Pharaohs, for the abundance of oil their seeds afforded; they are still grown to a great extent in that country at the present day. Pliny speaks of a turnip-rooted kind, and of a sweet and tender sort, and of one that continued good throughout the winter. Gerard cultivated four kinds of radishes in Queen Elizabeth's time.

*Uses.*—In the south of France the roots are roasted in wood-ashes; they are also used there in soups, to which they give an agreeable flavour. The Roman physicians recommended them to be eaten raw in a morning with salt, and before taking any other food, a practice in use in some parts of England at present. Radishes abound in a penetrating nitrous juice, which makes them diuretic, and cleansing to the intestines and viscera. They are considered also as excellent antiscorbutics. At present they are usually eaten raw with salt as a salad, with butter and cheese. The leaves are sometimes boiled as greens, and the roots make an excellent dish, when rather too large for a salad, by being boiled and served to table as asparagus. Neither the roots nor leaves, however, afford much nourishment. The roots are often sliced and added to mixed salads, and are occasionally eaten alone with salt, vinegar, and other condiments. The young leaves are also eaten along with mustard and cress, and for this purpose the seed is often sown in the same manner as they are. The seed-pods, when nearly full-grown, but still green and tender, are added to mixed pickles, and pickled alone as a substitute for capers.

*Propagation.*—The radish, being an annual, is propagated from seed.

*Sowing.*—As this salad is in request throughout the year, successional sowings must be attended to. Where there is the accommodation of a tanked pit or dung-heated pits or frames, a sowing for winter supply should be made every ten days from the beginning of November to the beginning of March. Where such conveniences do not exist, then for winter use a sowing should be made at the end of October, another about the middle of November, one at the end of that month, and others twice during Decem-

ber, January, and February; and from the end of that month sow every ten days, throughout the remainder of the season. These sowings have reference to the turnip-rooted and spindle-rooted varieties in ordinary use. For the black, white, purple, and brown Spanish sorts, which are hardy, and continue long fit for use after attaining their full size, these should be sown in August, and another crop in September, which will carry the supply through the winter, whether they be kept in the ground or taken up and pitted like potatoes. The seeds will in general germinate in less than a week, and in six weeks the plants will be fit for drawing.

The ordinary turnip and spindle-rooted sorts should be sown broadcast, whether in beds, in the open air, or in pits and frames. Avoid too thick sowing. Two ounces of seed will sow three lights of a pit or frame of the ordinary breadth, or the same quantity will sow a bed of 50 square feet in the open ground. They are often sown thinly between rows of potatoes in pits or frames, as they will be gathered off before the potatoes have attained a size to injure them. The hardy winter sorts should be sown in rows, as they occupy the ground much longer, and will require the surface to be frequently stirred up by the hoe. Cover the seed fully half an inch, and, in sowing in the open borders, avoid spilling any of the seed on the surface, as such will attract birds, which are very fond of them. Net the ground over to protect them; or, better, cover with wire-netting, which, although rather more expensive in the first instance, will be found the cheapest in the end. Both the tap-rooted and turnip-rooted kinds should be sown at the same time, as well as those differing in colour, to afford a greater variety in the salad. For late autumn, winter, and early spring crops, choose the warmest and driest border the garden affords; while for those for use during the heat of summer, a cool moist place should be selected.

The radish is one of the few exceptions to drill-sowing, which has for its chief principle the means afforded the cultivator for thinning his crops, so that each plant may have room to develop itself to the extent at which it should arrive, when

in its fullest state of perfection. The radish does not require this care, as the strongest seeds vegetate first, and the plants produced from them are daily withdrawn for use, thus leaving room for those which follow in succession. It is good practice to sow at the same time with the radishes such seeds as lettuce, leeks, parsley, &c., because these vegetate much more slowly than the radish, and as it is removed they come in in succession, and fill the space until such time as they are of such a size, and sufficiently hardened off, as to be fit for planting in the open border of the garden. Indeed, so great a difference exists in the germinating process of these seeds, that radishes, leeks, and parsley may be sown on the same day. When the first is withdrawn, the second takes its place; and when the plants are of a size to be transplanted to a nursery-bed, to fit them for final transplanting, the parsley comes in, which takes so long a time in germinating as to have given rise to the common but vulgar saying, "that parsley-seed goes nine times to the devil before it begins to grow." By following this rather unusual mode, time and space are economised; and as lettuce, leeks, and parsley plants are improved by transplanting, the advantages to them individually must be evident.

"The London market-garden practice for obtaining early radishes in the open air is to sow from the first to the last week in December, choosing as warm a situation for the purpose as possible. The ground being prepared, the seed is sown broadcast. The alleys are marked out, and the mould from them is thrown over the seed. A wooden rake is used to make all level; no iron rakes are used in market-gardens. After sowing, straw, which has been previously shaken out of the London stable-manure, is put over the beds 2 or 3 inches in thickness. When the plants come up, which depends upon the winter, the straw is removed every day, and put on every night, until all danger from frost is past. It takes 5° of frost to hurt a radish after it is half-grown."—CUTHILL.

It is only in the most favourable situations that radishes, with the exception of the winter kinds, can be advantageously grown in the open air during winter. Did they even, by covering or otherwise,

survive the frost, they would be hard and stringy compared with such as are grown rapidly on a mild bottom temperature; and, indeed, apart from their quality, what with covering and uncovering during winter, the cost in labour would be as much, if not more, than would attend their production in a heated pit or frame. Radishes grown in artificial heat require abundance of ventilation, and as little exclusion from the light by coverings as possible. The temperature should range from 48° to 58°, but may be increased to 70° with impunity; and tepid water should be frequently applied, for the radish is fond of moisture; but pouring cold water upon them, or any other forced vegetable, during winter, when the soil is already too cold, is extremely injurious.

*Subsequent cultivation.*—In the open air, radishes require protection during winter, either by the means practised by the London market-gardeners stated above, or by other means, such as hooping the beds over and covering with mats, &c., all of which we think are far behind the conditions of the present age. If they are wanted during that period, glass as a covering should be employed; and where that is the case, either a tanked pit, or frames placed over vegetable matter in a state of fermentation, may be employed; the latter of itself, when broken down by decay, will, as a valuable manure, repay the expense of collecting and working.

*Soil and manure.*—The soil should be deep, light, and mellow, and thoroughly pulverised by deep digging or forking, without which radishes will ever be hard and unfit for use, and this is more especially the case with the long or spindle-rooted kinds. Strachan, a writer in "The Horticultural Society's Transactions," vol. iii., p. 438, observes on this subject, "The character of a good long-rooted radish is to have its root straight, long, free from fibres, not tapering too suddenly, and especially to be fully formed on the top, or well shouldered as it is called, and without a long neck; the roots should be ready to draw while the leaves are quite small, whence the name of 'short-top radish;' and if they soon attain a proper size, and also force well, they are then called *early* and *frame* radishes." To attain these properties the soil should be

light and rich, but not made so by recent manuring, unless of a very decomposed description.

*Taking the crop and subsequent preservation.*—Radishes are gathered day by day, and hence serve the purpose of thinning; still they should on no account be sown thick; but, supposing the seed good, the plants at germinating should stand 1 inch or 1½ inches apart. The strongest-leaved ones, therefore, may be taken as the largest, but not always the best root; these should be drawn first. When collected and in the vegetable-house, they should be washed quite clean, the thready fibres, where they exist, cut close off, also a small part of the tips of the root, and all the leaves removed excepting two or three of the last-formed ones on the crown, which should be retained. Care must, however, be taken that the roots do not become too old and hard; a good criterion is to break them over, and if the parts separate freely, then they are fit for use; but if they do not, then they are too old for salad purposes. The winter or Spanish kinds should be dug up about the beginning of November, deprived of their tops, and pitted like potatoes, or buried in sand in the root-cellar. This sand, however, should not be too dry, for reasons given elsewhere.

*Approved sorts and their qualities.*—An excellent paper on the classification of radishes will be found in the 4th vol. of the "Transactions of the Horticultural Society," p. 13. By this arrangement they are divided into three classes, namely, *Spring and Summer kinds*, *Autumn kinds*, and *Winter radishes*.

The *Spring and Summer kinds* consist of scarlet or salmon-coloured—and its sub-varieties, short-topped scarlet, and early-frame scarlet; and to these we may add, as improvements on the originals, Wood's early frame, not very long, but very early, and well calculated for forcing; Beck's superb short-top, a long-rooted variety, of good shape and colour, with leaves particularly small; long white Naples, an improvement on the old long white cultivated in Gerard's time—a very good variety, and esteemed by some on account of its semi-transparent white colour. Purple-rooted only grown as affording a variety in point of colour.

Of *turnip-rooted sorts* we have the white and red; and of these some sub-varieties, particularly of the latter—such as the pink, rose-coloured, scarlet, and crimson, which are mere shades of difference in colour. The scarlet olive-shaped, a quick grower, tender, and considered rather milder than most other sorts. There is a grey turnip-rooted sort grown by some; we have found it to be merely a dirty white, and

the large and small yellow turnip-rooted variety stand no higher in our estimation.

The *Autumn kinds* are the round brown, large in size, not very handsome in shape, nor of a decided colour. White Russian, a very large sort, of good form, somewhat resembling a well-formed white carrot; in flavour resembling rampion. Not in general cultivation in Britain, but much grown in the north of Europe. The red metz, a French variety esteemed in the Paris markets, in which it forms the principal supply; roots of moderate length, rose-coloured, with few leaves, and those very small.

*Winter radishes.*—Of these, the best is the large Spanish black-rooted. The skin is black, with numerous white dots; irregularly pear-shaped; flesh white, firm, and solid; much hotter than any other kind. Esteemed on account of its hardiness, and as affording an agreeable winter salad when cut into slices. Large white Spanish; skin white, tinged with green; flesh firm, solid, and white; form oval; flavour hot and pungent. Purple Spanish is only a sub-variety of the black; the skin is purplish; flesh firm and white. Oblong brown, another sub-variety, with brownish skin; shape pyriform; plant very hardy. The Chinese rose winter radish is also a sub-variety of the white Spanish.

*Insects and diseases.*—The plants, when in their seed-leaf state, are preyed upon by the aphides, and other insects, which are destructive to all plants of the order Cruciferae: *vide* CABBAGE and TURNIP.

*General remarks.*—Some of the best plants should be saved from the principal spring sowing, for seed. Take them carefully up in May, preserving the leaves entire; select the most

perfectly formed roots, and transplant them into rows 3 feet asunder each way, inserting the roots with a large dibber so deep that their crowns will be just level with the surface of the ground. It is unwise to save seed from more than one variety flowering at the same time, as the plants are liable to hybridise with one another, and seed of the previous year's sowing should always be sown. To save seed of the winter radishes, some of the best-formed bulbs should be planted as above in March, and the pods gathered when they become brown and fully matured. Seed radishes must be covered with nets to protect them from birds; and if the quantity of seed to be saved is great, the whole stalks should be cut over, and, when dried, stacked by until there is time for thrashing them out. If the quantity is small, the pods may be cut off individually as they ripen. "The seeds of the different varieties are easily distinguished by an experienced seedsman. Those of the long white radish are small, flat, and pale; of the scarlet and purple long-rooted, large; and of the first very light coloured, compared with those of the latter; of the white turnip, small, round, and brown; scarlet turnip rather larger, and somewhat darker; purple turnip larger and brown, being similar to the long-rooted purple, except in size."—*Cottage Gardeners' Dictionary*, p. 762. The pods for pickling should be taken when nearly full grown, but still soft and green, which will in general be the case in August.

The European names are—Radis or Rave in French; Rabano in Spanish; Rettig in German; Rafano in Italian; and Tamme radijs in Dutch.

## CHAPTER VII.

### ESCULENT-ROOTED PLANTS.

#### § 1.—THE CARROT.

*Natural history.*—The carrot (*Daucus carota* L.) belongs to the natural order Umbelliferae, and to the class Pentandria and order Digynia in the Linnæan arrangement. The generic name is derived from *Daio*, to separate, because it dispels flatulency; the specific name, *Carota*, is from the Celtic *Car*, red, the colour of the root. The carrot, in its wild state, is indigenous to many parts of Britain, generally in sandy or chalky soil; when and how it became reclaimed, or elevated to its cultivated state, is not now known. In that state it was known to Dioscorides and Pliny; and the latter informs us, book xxv. chap. 9, that the best kinds came to Rome from Candia, and the next best from Achaia. Theophrastus, in the 9th book of his "History of Plants," says that the best carrots are found in Sparta. Gerard calls these plants *Daucus cretensis verus*, or *Candia carrots*, and says that the true *Daucus* of Dioscorides does not grow in Candia only, but is found upon the mountains of Germany, and upon the hills and rocks of Jura, about Geneva. It is possible, therefore, that Britain received her first supply from the latter situation. Later authorities think that the carrot was introduced into this country by the Flemings, in the time of Queen Elizabeth, and that they were first sown about Sandwich, in Kent. Of one thing we are certain, that carrots, as well as several other culinary vegetables, were imported to London, from Holland, during Elizabeth's reign, and moreover that the leaves of carrots were used in the head-dresses of the ladies of her court, in imitation of those of previous date, who employed the leaves of the wild carrot for a similar purpose.

*Uses.*—Few vegetables are in greater demand for culinary purposes than the carrot. It is used in soups, in stews, as a vegetable dish, and even in puddings; and so much are young carrots in demand in good cookery, that they are supplied throughout the summer from the open ground by repeated sowings, and during winter by artificial heat. In some parts of England carrots are served up with fish, as parsnips have long been, during Lent. Both the seed and the roots are used in medicine, the seed of the wild carrot being considered one of the most valuable diuretics of native growth. The roots of carrots

contain a large portion of saccharine matter, and have been used in the manufacture of sugar, and in distilling, all over the Continent, where their cultivation has been longer and more extensively pursued than in Britain. Excellent bread has been made of white carrots, when washed and boiled, and mixed with flour in equal proportions by weight: such bread will keep good for a week.

*Propagation.*—Although the carrot is a hardy biennial, the roots, which are the only part used in domestic economy, are fit for use the same year. Seed must therefore be sown annually, they admitting of no other mode of propagation.

*Sowing.*—A small sowing may be made about the beginning of February, choosing a warm dry border, with a view to have young carrots fit to draw for use by the beginning of May; and another should follow about the middle or end of the month, and again a larger sowing by the first week in March: the state of the weather must, however, regulate these. These periods are adapted to southern culture; in the north, it is seldom that seed sown previous to the 1st of March repays the trouble. Crops sown so early in the season will derive considerable benefit from the ground being covered with dry litter during the continuance of frosts. The early horn only should be employed for these early sowings. For general crops, the middle of March and during April is a proper season, taking advantage of the ground when it is dry. For a supply of young carrots during winter, sow on slight hot-beds in December, January, and February. The two later sowings will be the most satisfactory. The end of April, and even the middle of May, is preferred by many for getting in their principal crop, they thinking thereby to escape the

attack of the carrot maggot, *Psila rosæ*: this, however, depends to some extent on the season, for cold and late springs have their effect upon the insect as well as upon the germination of the plant. Many also defer till the beginning of May, from the apprehension that, if the seed is sown earlier, the plants will be liable to run to seed. Sow again in June and July, and lastly towards the end of August or beginning of September—the later crop to supply autumn demands. Some depend on this sowing for a winter supply, substituting them for young carrots, for which they are a poor representative, except in form, being devoid of the same flavour and colour; and although they may pass with some for such purposes, they will not escape the keen eye of a French cook. Forcing carrots during winter is no serious matter, if the conveniences of hot-beds or tanked pits be at command; and those who will not go to the expense of such conveniences must just go without, or be content with such as are produced by late sowing, and kept in the ground till they are wanted. One great advantage arising from not sowing too early, is that the seed has a much less time to lie in the ground before germinating, and hence braids as soon as the weeds, and therefore admits of earlier hoeing; whereas, if very early sown, the weeds get the start of the young carrots, and render the operation of cleaning them more tedious and less effective. The seed does not come up for four or five weeks in spring, and for three or four in summer and autumn. The seed of chickweed, and many other weeds, vegetates in much less time in the same temperature, and hence the propriety of bringing on an artificial germination, as afterwards to be noticed, reconciling as near as may be the germination of the carrots and the weeds.

The ground intended for this crop should be trenched not less than  $2\frac{1}{2}$  feet in depth, and well pulverised during the operation. It should be in a sufficient state of enrichment from the manuring of the previous crop; hence the ground from which celery has been removed is deemed the best, on account of its having been well wrought during the previous summer and autumn, and also as having been sufficiently enriched. Notwithstanding this, trenching is desirable; and if this opera-

tion has been carried on as the ground became vacant, and thrown up in rough ridges, so much the better, as all that will be required at the period of sowing the carrots will be to level down the ridges and break down the clods with a coarse rake, rendering the surface sufficiently level and smooth for the drawing of the drills; for carrots should, for principal crops, be always drill-sown. When the ground is dry and prepared as above, the drills may be drawn with the drill-rake in the way described under section ONION, p. 33; a very slight pressure will give them the proper depth—an inch and a half. The distance at which the teeth should be set depends on the distance the rows are to be apart from each other; 9 inches being the usual distance for horn carrots, and 1 foot for the larger-growing kinds. The head of the drill-rake being marked off in inches, the three screws are to be slackened, the teeth set at their respective distances, and the screws to be tightened up again.

Previous to sowing, the seed should be well separated by rubbing between the hands with an admixture of a little dry sand, or finely-sifted coal-ashes, without which preparation the seeds would not separate freely, and hence the crop would come up unequal and patchy, besides wasting much of the seed. A quiet still day should be chosen, as the seed is so very light that it would be liable to be blown away before it could be covered in. Sow thinly in the drills; and as the seed is committed to them it should be covered in immediately: by walking along each drill with a foot on each side of it, and by drawing the feet along, one after the other, the process of covering will easily be effected; or, if the ground is wet, by going down every fourth or fifth space, the same number of drills may be covered by the head of a wooden rake. In this state the ground should be left; all scratching and raking, after the seed is sown, is so much labour thrown away, and the ground anything but improved by the operation. In extremely light soils it may, however, be slightly footed over, or trod in, as it is technically termed, because such soils are improved mechanically by the process of compression; hence in old and long-wrought market-gardens, where the soil is soft and spongy, a light wooden roller is

employed; and indeed, in large private gardens, rolling is a more business-like way of performing the operation, and involves a less expenditure of time.

It is a common practice with carrot-growers to assist the germination of the seed—a process by which several days are gained, and which is of advantage in late wet springs, and also in gardens, where the ground may not be prepared, or where the previous crop has scarcely been removed from it. This process is effected by mixing the seed with damp sand, and placing it in a warm situation, such as on the floor of a hothouse, or indeed anywhere else, if in a temperature from 10° to 20° higher than the soil into which it is to be sown. Others place the seed in a bag, and steep it in rain-water for about forty-eight hours, eight or ten days before sowing is to take place. If in quantity, and spread out on a floor to the thickness of 9 or 10 inches, it will of itself generate sufficient heat, by a slight fermentation which will take place in consequence of being thus wetted, to cause the seeds to chip or germinate; but if in small quantities, it had better be laid upon a floor, or in shallow boxes, in some warm room, until this takes place. In either case, great care must be taken that germination is not allowed to go too far, else, in the process of sowing, the germs of vegetation will be liable to be broken off, which will destroy the seed. In careful hands, this is a process in seed-sowing which might be advantageously applied to all seeds that are long in vegetating. On the principle of simultaneous cropping, many market-gardeners sow a thin crop of radishes broadcast along with their carrots; the former come off for use before any damage is done to the latter. The carrot-seed, when not prepared as we have stated, will, early in the season, lie in the ground for five or six weeks before they come up, while the radishes seldom lie above a fortnight. Others, particularly private gardeners, sow a thin sprinkling of leek-seed along with the carrot, which may be done in the same drill, to admit of early hoeing. Others sow onions, and instances have been known where cabbages, savoys, or Brussels sprouts have been planted in the same line, and at 4 or 5 feet apart, as well as where planted promiscuously over the ground, in which the carrot crop has escaped the attacks of

insects, while crops adjoining, sown alone, have been completely destroyed. We have seen a case of this sort, in the very old garden of the Earl of Morton, which has probably existed as such for two centuries, on which as fine clean carrots were produced as could be wished, and not for one season only, but for several consecutive years; and we were informed by Mr Smeal, the gardener, that before he practised planting brassicaceous plants along with his carrots, none had been produced previously in the garden, in the recollection of the oldest person living at Dalmahoy. The Brussels sprout is the best for this purpose, as it grows tall and slender, and shades the carrots less than any of the spreading sorts.

Carrot-seed is more liable to be bad than most other garden-seeds; it will, therefore, be a wise precaution to sow 50 or 100 seeds in a flower-pot, and place it in the heat of a mild hothouse to vegetate. By counting the number of plants which come up, the quality of the seed will be correctly ascertained. One ounce of seed, if good, will be sufficient for a bed of 130 square feet, if sown broadcast; and if sown in drills, the same quantity will be sufficient for 150 feet.

*Subsequent culture.*—When the broadcast-sown crop comes above the ground, it should be thinned out with the 2-inch draw-hoe; this hoeing, however, is more to suppress weeds and keep the surface of the ground open; the principal thinning should take place when the plants have attained the height of from 2 to 3 inches, and then they should be singled out to from 4 to 5 inches, clearing the ground at the same time of every weed. This will admit of after-thinning for immediate use; and, should the demand not require them in sufficient time, then a third and final thinning should take place, leaving the horn sorts 6 or 7 inches apart, and the large-growing sorts 9 or 10 inches. Those of the former, in drills, may be left at 5 or 6 inches apart, and the latter at from 6 to 8 inches.

Much as we advocate deep-stirring the ground between the rows of crops generally, the carrot forms almost the only exception, as, by so doing, it encourages the lateral fibres to grow large, and produce what is technically called forked roots; flat-hoeing, however, for the

suppression of weeds, must be attended to.

*Soil and manure.*—A light deep sandy soil is natural to the carrot; in fresh loamy soils it also flourishes in great perfection; a cold stiff clayey one is the least of all adapted to it, and in such soils expedients like the following are sometimes had recourse to—namely, to thrust a long dibber, such as is used for planting horse-radish, into the soil, filling up the perforation with sand, and dropping 3 or 4 seeds into it, to be thinned out to one, after they have attained the height of 2 inches. In this way, carrots of large size have been obtained. In well-drained peaty soil, they have been successfully grown, and in such are usually free of disease, or the attacks of underground insects. In strong soils, they are often difficult to get up: to aid them in this, deep drills are drawn, and filled with light soil, such as leaf-mould, in which clean sea or river sand has been incorporated; in this the seeds are sown, and vegetate freely, and establish themselves until of a size and strength to penetrate the stronger soil below. The manures best suited to this crop are those in a liquid state, applied during growth: stable-yard manure, unless in a very decomposed state, should not be applied; and to keep it until it is in a proper state for this crop is an evident waste of its fertilising powers, which had much better have been employed in the feeding of the previous crop. The application of fresh manure causes them to grow forked and misshapen, as well as to be attacked by insects: the only manure we apply, and even that is seldom, is a light dressing of pigeons' dung; guano may also be applied with advantage, especially if in a liquid form. The experiments made some years ago by Mr C. W. Johnston, on the application of salt to various crops, gave the following result in the case of carrots: Light sandy soil, manured with 80 bushels of salt, and 20 tons of stable-yard manure per English acre, yielded 23 tons 6 cwt. 1 qr. 18 lb.; the same extent, with 20 tons of manure, only 22 tons 18 cwt. 0 qr. 26 lb.; manured with 20 bushels of salt, only 18 tons 2 cwt.; without any manure or salt, 13 tons 4 cwt. Salt and soot is a favourite manure for carrots, and the quantity applied may be to the extent of 10 bushels of salt and

20 bushels of soot per acre. Turf-ashes, and the ashes of wood and garden-refuse, have been found beneficial when applied in a newly-formed state to carrot, onion, potato, and beet crops; they contain silica, alumina, oxides of iron and manganese, sulphates of potash and lime, phosphates of lime, magnesia, common salt, and charcoal; they should not only be dug into the ground, but sown also on the surface, previous to drilling, by which means they come in immediate contact with the seed.

*Forcing.*—To obtain carrots in a young state, fit for use during winter, artificial means must be resorted to. A mild hot-bed of dung and leaves, or a tanked pit, is the proper accommodation for their seed; therefore, if the true early horn, which is the best suited for forcing, as well as most approved of by cooks, should be sown at the periods stated above, either the tank or bed should be covered, to the depth of 9 inches, with light rich sandy soil, and the seed sown in the broadcast manner, and covered about half an inch with sharp dry sand; a temperature ranging from 55° to 65° will be sufficient, and instead of raising this temperature by additional fire-heat, during frosty weather, rather cover up the glass roof to exclude the extra cold. Where a less abundant supply is wanted, seed may be sown in shallow pots, and these placed in a mildly-heated pit, close to the glass. Radishes and young onions may be obtained in the same manner.

The London market-gardeners' practice is to sow the early horn only, in frames and beds to be hooped over, and covered with mats. A sowing is made in November, and another in January. When the plants are up, they are thinned to 4 inches apart. The hooping-over and mat-covering practice is behind the intelligence of the present times. Private gardeners act better, and grow their winter carrots under the protection of glass coverings, either in pits or in frames.

*Taking the crop, and subsequent preservation.*—Carrots should be taken up on the approach of winter, and when their growing season is over. To leave them in the ground injures their flavour and colour; and if so left after the turn of the year, they begin to become hard, fibrous, and ultimately, when their spring growth commences, unfit for use. Besides, it is evi-

dence of bad cultivation to allow any ground to be occupied with a crop during winter, which might as well be dug up and stored by, and so give an opportunity for the improvement of the soil by manuring, trenching digging, &c. Dry weather should be chosen for taking up the crop, and the implement employed for loosening them in the soil should be a fork, and not a spade. When they are withdrawn from the ground, the tops should be cut off: on this part of their management opinions are somewhat at variance, some recommending cutting the tops off an inch from the crown, others close to it; while some say a slice about the thickness of a shilling of the crown of the root should be removed at the same time. Those who advocate the latter process, do so with a view to prevent any further vegetation; while others say that thus cutting into the root causes it to rot. Those who favour the former do so with a wish to preserve the capability of vegetation, though certainly not to encourage the tendency to grow. In either way they will keep equally well, if dried in the sun when taken up, and pitted, like potatoes, in long narrow pits, or packed in sand not over dry in the root-cellar, placing 3 or 4 inches of sand between each layer of roots; for both here and in pits, if laid in thick masses together, fermentation takes place, and in a short time the whole will become a mass of putrefaction. Their keeping till spring depends greatly on the low temperature they are kept in, and also on vegetation not being encouraged. When packed in sand, they can readily be examined during winter; and should any signs of vegetation appear, the embryo leaves can be rubbed off. Packing them in too dry sand has a tendency to absorb the natural juices in them, and cause them to become hard and tough, and indeed unfit for use. Although they will keep in the ground all winter unscathed by frost, yet, when taken up and exposed to it, they are very susceptible of injury from it. In storing carrots for winter and spring use, we may observe that all the small fibrous roots should be cut clean away, as, if left on, they are liable to decay, and cause the decay to spread through the whole bin. In cutting off the tops at lifting, remove a slice from the crown sufficiently thick to divest them of those latent buds which

surround the crown, and which would burst out into leaves and begin to grow upon the least rise of temperature in the bin or cellar. Carrots so treated do not wither, owing to the evaporation from the wound; nor do they at all decay. If allowed to sprout into growth, the natural sap is drawn from them, and they become hard, dry, and destitute of flavour. If carrots are left in the ground all winter, they should, on the approach of severe frost, be covered over with litter; for it not unfrequently happens, if left unprotected, that the frost will destroy them.

*Approved sorts and their qualities.*—Carrots are divided into two pretty distinct classes—namely, Horn carrots and Loug carrots; the former are nearly cylindrical, terminating abruptly at the point: being considered of superior flavour and delicacy, they are preferred for garden culture. The latter have long tapering roots, are of larger size, and are more fitted for field culture than for domestic purposes.

*Early or common horn.*—The most esteemed of all garden carrots for general culinary purposes, on account of the smallness of its heart and tenderness of its fibre; form thick, short, and terminating abruptly. Crown hollow, with very small neck and short thin foliage. Known also as Dutch carrot, or Dutch horn. Average size from 6 to 7 inches in length. Is the same as the early scarlet horn.

*Early forcing horn.*—Root somewhat conical, seldom exceeding 3 inches in length; well adapted for forcing for winter use.

*Early short horn.*—This appears intermediate between the early forcing and orange carrot in size, shape, and period of arriving at maturity; probably a hybrid between them. It appears to be little known in Britain, but is much grown on the Continent, where it is known as Carotte courte hative, and in our seed-shops as red horn, short red, and short orange.

*White Belgian horn.*—Resembling the last, except in colour. A delicate and excellent sort; but its colour is objected to by cooks. Is also known as transparent white.

*Long red horn.*—Merely a variety found in seed-lists, differing little from the first. Is known also as long red horn.

Of Long carrots, the following are most in estimation for culinary purposes—

*Altringham.*—“This sort is easily distinguished from the orange and long red by its roots growing more above ground, also by their having more convex or rounded heads, tapering rather more irregularly and terminating more abruptly at the point; in colour most resembling the orange, but having a smaller heart. This variety is more difficult to procure genuine than any of the others, from its being remarkably liable to sport, even although the roots grown for seed be selected with the utmost care.” It is of Cheshire origin, having appeared at Altringham, a village in that county, about

forty years ago. It is known also as green-topped and superb.

*Long red.*—Colour deep red; heart small; roots long, not remarkable for their thickness. A popular sort in some parts of England, where it is known as long Surrey, Surrey, Chertsey, and Studley. It is the Carotte rouge longue of the French, and pretty extensively grown over the Continent.

*Long orange.*—A large variety, less esteemed for culinary purposes than the red sorts, on account of its colour. It was formerly much grown in gardens in Scotland. The roots are produced entirely under ground, and it is, therefore, less liable to the attacks of hares than those which grow partly above ground. Roots thick at the top, regularly tapering to a point. Heart large, hard, and not readily softening in boiling. It is known as the large red, large field or cattle carrot, Sandwich, and is the Carotte rouge pale de Flanders.

*Purple-coloured.*—Roots of medium size; deep reddish purple; heart large and yellow. It is better suited for wet soils than any other, and in such is often cultivated by the French. It is known also as red, deep red; and is the Carotte violette, La violette, &c. of the French seed-lists.

*White.*—Seldom grown in gardens. Of it there are two varieties, the common white, not worth cultivating, and the large white green-top. Produces immense crops, and is delicate and well-flavoured when cooked, but does not keep well through the winter. The large white green-top has roots short, of large size and great thickness while under ground; greenish-coloured on the top, which rises considerably above the surface. On account of the shortness of its roots and their standing so high above the ground, it is better suited for shallow soils than any of the others. The French possess a much greater variety of carrots than we think worth cultivating in Britain.

*Insects and diseases.*—"Insects infest the carrot crop in the root, stem, and flower. The plant no sooner makes its appearance than it is attacked by aphides, which are scarcely larger than cheese-mites, of a uniform pale-green colour, with six legs, two horns, and no wings. Their presence is indicated by the yellow foliage, and in pulling up the plant the roots are sound and clean; but the crown is not only discoloured, but, on opening the embryo leaves, numbers of the aphides are found concealed. Dusting the crop on the appearance of the aphides with caustic lime is a good remedy.

"The root of the carrot is affected by a disease named the *rust*, in which the crop gradually dies off, loses its saccharine qualities, and, changing to a ferruginous colour, becomes of little value. This complaint is occasioned by the larvæ of the carrot-fly, *Psila roseæ*, fig. 61, eating galleries along the roots, which they inhabit through the summer, when they become pupæ in the earth; but a new brood hatches in the summer every three or four weeks. This fly is 3 lines long, of a pitchy black; the wings lie horizontally along the back when at rest, and extend beyond the tail, and when expanded extend to 5 lines. The maggots are ochreous and

shining, cylindrical, pointed at the head, and obtuse at the tail, resembling cheese-hoppers, though they cannot leap, and are exceedingly transparent, every internal part being visible.

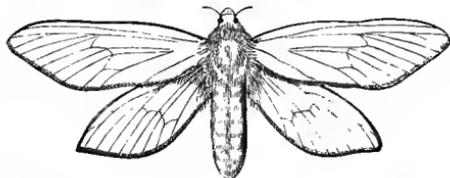

Fig. 61.

CARROT-FLY.

When the cavities have been opened by this maggot in the rest of the carrot, large numbers of the millipede (*Polydesmus complanatus*), and of the centipede (*Scolopendra electrica*), assist in extending the depredations. Another caterpillar, the larva of the ghost-moth, *Heptalis humilis*, fig. 62, also eats into the root of the carrot and injures it. The larvæ of the flat-body moths,

Fig. 62.

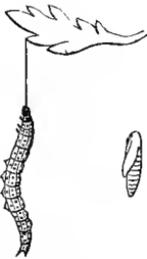

GHOST-MOTH (MALE AND FEMALE), CATERPILLAR, AND CHRYSALIS. Natural size.

*Depressaria cicutella* and *depressella*, bore into the stems of the carrot, causing the leaves to stunt and decay; and the larvæ of the grey carrot blossom flat-body moth, *Depressaria dau-cella*, commit great havoc on the umbels of the flowers."—*Book of the Farm*, vol. ii. p. 96.

*Depressaria applana*.—The common flat-bodied moth, fig. 63, is another of this genus of moths whose caterpillars do great mischief to seed-crops of carrots and parsnips, by devouring the whole umbels of flowers, and not infrequently stripping the plants of their entire stem foliage.

Fig. 63.

COMMON FLAT-BODIED MOTH, CATERPILLAR, AND CHRYSALIS.

Their mode of operating is to draw the flower-heads together by many strong silken threads, which they afterwards extend into a network habitation, in which they remain consuming the seed-vessels, and after a time changing to pupæ, sometimes within the

web, at other times rolling themselves up in a leaf or within the stem, in which they remain secure.

The wire-worm (*Elater*) also attacks them under ground from their earliest stages. Copious applications of caustic lime are of much use in such cases; and highly-stimulating manures, such as guano or pigeons' dung, accompanied with deep-trenching, will be found beneficial—the former to stimulate the carrots into rapid growth, and the latter to derange the economy of the insects during their transformation.

Amongst other means of getting rid of the wire-worm is the rather novel one of feeding it with rape-cake to repletion. The rape-cake is broken up into small pieces about the size of marbles; and when the finer particles are removed by sifting, the larger pieces are sown in the drills at the same time as the seed; or a better way is to drill the ground from 3 to 4 inches deep, and in these drills to sow the rape-cake, covering it up and drilling again at the usual depth for the carrot-seed. The month of March or beginning of April is the best time to sow the rape-cake, and which may be done weeks before the carrots are sown, because at that time the worm is resuming its depredations after awakening from its winter torpid state. The drier the season the more effective it will be in destroying the worm, as the cake will not so soon dissolve as it would in wet weather. The insect will devour it greedily, and continue to do so till it actually dies of repletion. Small pieces of rape-cake fastened to the end of a wooden skewer, and placed from 3 to 5 inches in the ground, form an excellent bait

for catching this insect, managed as we have noticed at p. 69.

Old garden-soils have been long considered unfavourable for carrots, and as a remedy in such cases, it has been recommended to trench the ground 18 inches in depth, and to fork into the bottom of each trench quicklime laid over it to the thickness of an inch, applying it in autumn. In spring, at the period of sowing, a slight dressing of quicklime is laid on the surface, and mixed with the soil during the process of drilling and sowing. The rationale of this appears to be, that the lime acts chemically upon the inert matter contained in most soils in which a superabundance of humus exists, bringing it into a more active condition. It is possible that sharp river or sea sand would have much the same effect. Active manures, such as guano and pigeons' dung, act much in the same way, and excellent carrot crops have been produced when the latter has been laid on from 3 to 4 inches in depth, and thoroughly amalgamated with the soil.

To save seed, transplant the roots, if the weather will permit, about the beginning of January; set them in rows 3 feet apart, and the roots 2 feet distant in the line; and that they may have sufficient scope to work in, trenches at least 1½ feet in depth should be dug and the roots set in them, placing in the bottom of each trench a slight dressing of decomposed manure or a thin sowing of guano. If the ground on which the crop has been grown is in sufficient condition to mature the crop of seed without manure, it would be advisable to mark the carrots at the above distance and to dig up all the rest, leaving them where they grew from seed. This may safely be done if the crop at taking-up indicates proper form and pureness as to variety; if otherwise, it is better to take them up entirely, and select the best-formed roots for replanting. The best seed will be produced where the plants are sufficiently apart to admit light and air amongst them. The first seed which ripens is also the best, and in moderate situations will begin to ripen about the 1st of September, when care must be taken that all the heads as they ripen are cut off with a sharp knife and placed under covering to dry. The umbels of seed, if once wetted by rain when nearly ripe, will often rot altogether; or if not, the seed will be of a bad colour and of inferior quality. As the seed dries it should be rubbed out and stored by for use; it is injudicious to thrash it, unless the quantity be very great, and that with a very light flail, as the seed is apt to be injured by the process. One plant saved for seed will be sufficient for a small garden, and so on in proportion to size.

*General remarks.*—The European names are—Mohre, or Gelbe rube in German; Carota in Italian; Carotte in French; Geel wortel in Dutch; and Chirivía zanahor in Spanish.

“The nutritive matter contained in a crop of 25 tons, or 56,000 lb. per acre of carrots, consists of husk or woody fibre, 1680 lb.; of starch, sugar, &c., 5600 lb.; of gluten, &c., 840 lb.; of oil or fat, 200 lb.; and of saline matter, 800 lb.—STEPHENS *ex* JOHNSTON'S *Lectures on Agricultural Chemistry*, second edition, p. 928.

## § 2.—THE TURNIP.

*Natural history.*—The turnip (*Brassica rapa* L.) belongs to the natural order Cruciferae, sub-order Orthoploceae, and tribe Brassicæ or Orthoploceae siliquosæ, and to the class Tétradymania and order Siliquosa. The generic name is derived from *Bresic*, Celtic name for the cabbage. It is found wild in various parts of Britain, chiefly in corn-fields and cultivated places. The ancient Greeks, to whom the turnip was well known, called it Gongyle, from the roundness of its root. At what period it became known in Britain, where it came from, or how its improvement from its native wild and useless state was brought about, is unknown. It appears to have been well known in Greece in the time of Democritus and Dionysius. Both the Greeks and Romans were well acquainted with its cultivation; and there are also faint traces in history that it was brought from Gaul and other northern provinces of the empire to Rome. It is also well known that, during the fifteenth century, the Flemings were considerably advanced in the art of cultivation, and that the turnip formed one of their important crops. From the remarks of Gerard, it would appear that turnips were not grown much in his time, except for domestic purposes. "It groweth," he says, "in fields and divers vineyards and hop-gardens in most parts of England. The small turnip groweth by a small village near London, called Hackney, in a sandy ground, and are brought to the Cross in Cheapside by the women of that village to be sold, and are the best I ever tasted. The bulbs, or knobbed root, which is properly called *Rapum*, or turnip, and hath given the name to the plant, is many times eaten raw, especially by the poor people in Wales, but most commonly boiled." The early Dutch white turnip is that noticed by our earliest horticultural writers. This, coupled with the well-known fact that, in Elizabeth's time, turnips, as well as other garden products, were quite common articles of importation to the English court, leads us to believe that our first garden varieties were introduced from Holland and Flanders, probably in the preceding reign. Those used for agricultural purposes were introduced long afterwards, mainly through Lord Townsend, who, when ambassador to the States-General in 1730, seeing the importance of this plant as there cultivated, introduced both the plant and its cultivation into his own estate in Norfolk. In "Miller's Gardeners' Dictionary," 3d ed. fol. 1737, six varieties of garden turnips only are described, two of which, "the round turnip with a white root, and the round turnip with a purple root," he says, "are cultivated for the table in England." The introduction of the Swedish turnip, often grown in gardens in cold localities for winter and spring use, where the other sorts would perish, for the excellent greens or tops it produces, when other greens are scarce, and which are now also blanched and forced as a substitute for sea-kale, is more clearly traced; but whether it is of Lapland or Swedish origin, is not so satisfactorily determined. Sir John Sinclair says it was introduced to Scotland in 1781-2 from Gottenburg;

others date its introduction from the same place at a somewhat earlier date. Miller, in the work quoted above, describes a yellow garden-turnip, and that it, as well as a long-rooted sort, "were formerly more cultivated than at present" (his time), "for it is now very rare to see either of these brought to the markets, though some years since they were sold in as great plenty as the common sort." The conjecture, therefore, by Professor Low, in "Elements of Practical Agriculture," p. 290, with regard to the yellow turnip, that it was a cross between the white turnip and the Swedish sort, admits of doubt. Yellow turnips being well known about the beginning of the eighteenth century, may have formed the type of most of those of the present day having globular roots, as, no doubt, the whites of the same period did of the majority of white globular ones as at present grown. Nor are we justified in presuming that the first removes towards improvement, in either case, took place in Britain, as at that time turnip cultivation was much more extensively pursued and understood in the Netherlands than it was with us in our then rude state of cultivation. In improved varieties, as well as in improved cultivation, Scotland, as far as regards this plant, stands pre-eminent at the present day. "Mr Morton, and the most eminent English authorities, now admit one turnip of Scotland to be equivalent to two of England; and that they cannot, in the latter country, raise turnips equal to those grown in Scotland. This superiority (of not only the Swedish, but other varieties) is not solely to be attributed to the soil and climate being more favourable to their growth, or to any improved method of cultivation adopted—these undoubtedly exercise considerable influence on the crop—but the principal cause of the superiority is to be traced, unquestionably, to the care bestowed in the growth of the seed."

*Use.*—The use of the root in broths, soups, stews, or entire and mashed, is general in all temperate climates, and also the use of the tender radicle and stem-leaves, and the points of the shoots when the plant is coming into flower, as greens (or turnip-tops). The seedling-plants, when the rough leaf is beginning to appear, like those of all others of the Brassica family, are used in small salading. The earliest crop of turnips (without forcing) comes into use about the end of May or beginning of June" in the neighbourhood of London, and ten days or three weeks later about Edinburgh; "and a succession is kept up throughout the summer by subsequent sowings; and turnips may be had through the winter, partly from the open garden, and partly from roots stored up in the manner of potatoes. Hence a large portion of the kitchen-garden is devoted to this crop. A well-grown turnip has a large smooth symmetrical bulb, a small neck, and a small root or tail, with few fibres, except nearest its lowest extremity."—*The Sub. Hort.*, p. 647. Boiled turnips, mashed or whole, is the orthodox accompaniment to a boiled leg of mutton. In the time of Henry VIII., turnips were used baked or roasted in the ashes, and the young shoots were used as a spring salad in those days, as well as boiled as a substitute

for spinach. They make an excellent white soup. In France they are served as a sauce for ducks, and are much used for garnishing tongues, hams, stewed beef, &c., being cut into roses and other devices. Turnip-tops, in spring, are the most wholesome of all green hardy vegetables, acting as a powerful antiscorbutic. The first settlers in Virginia were greatly afflicted with scurvy, until they were able to cure themselves by the turnips they cultivated. Turnips are nutritious and wholesome, and certainly ought to occupy a place on our tables more frequently than they do, particularly in Scotland, where the best turnips are grown and the fewest eaten; and this the more so, as potatoes are neither so nutritious, so wholesome, nor are they now so abundant. Turnips have also been converted into meal.

The French turnip, or *navet*, yellow or petit Berlin, is much cultivated all over the Continent for culinary purposes, and forms an important ingredient in almost all foreign soups. Stewed in gravy or stock, it is much prized; few dinners are served at which it does not in one way or other appear. The peculiar flavour is in the outer rind, so that, in using it, it should not be peeled. It was at one period much cultivated in Britain for cooking purposes, and is mentioned by Justice of Chichon as giving a higher flavour, if two or three are used, to dishes, than a dozen other turnips. It is occasionally met with in the London market, both of home growth, and also imported from Berlin and Altona. It is in demand in all families where high cooking is practised.

The bulbs, taken up in the beginning of winter, and planted in any light soil, rotten tan, or leaf-mould, and placed in dark cellars, the floor of a mushroom-house, or indeed anywhere, where a temperature of from 50° to 60° can be maintained, and light excluded, will send up their leaves in profusion, which, when from 6 to 9 inches high, and blanched white, form an excellent substitute for forced sea-kale—a luxury any one may enjoy by purchasing a few dozen roots in November, and growing them as above in a cellar, stable, or outhouse, in a moderate temperature, and in darkness.

*Propagation.*—By sowing the seed where it is to remain, excepting in the case of the Swedish or Rutabaga and Teltow, which readily admit of transplanting.

*Sowing and planting.*—For the earliest crop, seed of some of the most approved early varieties should be sown on slight hot-beds about the 1st of February, and treated as already recommended for radishes, p. 172. The first crop in the open air may be sown in the middle of March in England, the first week in April in Scotland, in both cases choosing the warmest border the garden affords. These will come into use, in the former case, in May and June, and in the latter about the end of May to the end of June—much, in all cases, depending on the locality, for there are some

where it may be considered early if fit for use in July. A second sowing should be made about the middle of April in the one case, and the end of the month in the other. The first principal summer crop in both cases should be made from the middle to the end of May, for crops to come in from the beginning of July, and last throughout most of August. Sow again in June and July for the principal autumn crops; and indeed, in many places, it is sufficiently late to sow at the end of July for such as are to be used during winter. For nice small roots, to serve during winter and until spring, a sowing should be made on a well-exposed spot, both in the second and also in the third week in August; and in situations so favourable as around Edinburgh, and along the sea-coast, a last sowing should be made about the middle or towards the end of September. This last crop we sow broadcast, and find them succeed very well, to be drawn for use through the winter, about the size of from a pigeon's egg to that of double that size. These also last much longer in spring, when taken up *before* vegetation commences, and buried in deep pits in a cold shaded place, to retard their growth. They serve for soups, and for that insatiable source of consumption, a *French cook's stock-pot*. Where very small young turnips are in constant demand, two or three intermediate summer sowings will be required; but these need not be so extensive as the general ones. It is unwise to depend for such a supply on the thinnings of other crops, because all turnips should receive their final thinning long before they are fit for such a purpose; and leaving them to attain the necessary size would only injure the principal crop.

The French turnip, or *navet*, should be sown during the first and third week in April, the first and third week in May, and again the second and last week in June, choosing the poorest light sandy soil.

The two earliest spring-sown crops should be sown broadcast in 3½-foot wide beds, for the convenience of affording temporary shelter in the event of late spring-frosts, and also because they are to be drawn young, and do not occupy the ground long after they are up. The latest crop of all may be sown in the same manner over the ground, without its being divided into beds; for, unless the

ground is in a very bad state, they will require no further care after thinning with the turnip-hoe, fig. 64, as the season

Fig. 64.

TURNIPI-HOE.

of weed-growing will have about ceased ; besides, their leaves covering the ground will tend to keep weeds down. All the

other crops should be sown in drills, 1 inch in depth, and at a distance between according with the variety, as some have very small leaves, like the Maltese, while others have them larger, like the Robertson's yellow-stone, &c. For the former, 1 foot is sufficient, thinning out the plants to 6 inches apart ; while for the latter, 18 inches between the rows, and 10 inches from plant to plant, will be a proper allowance when thinned out for the last time. In all crops there is an evident mistake in too close cropping, and in few more so than in the turnip. These distances would be ill adapted for field cultivation, where bulk of crop is the object aimed at : the case, however, is different in garden culture, where no turnip should exceed the diameter of 4 inches ; and from 2 to 3 inches is a better size. The ground should be in a highly-enriched state, that quick growth may be induced. It is of vast importance, in securing a good braird, and also a means of escaping the fly, that vegetation should be rapid. This naturally ensues when the seed is sown immediately before rain ; but as this cannot be at all times calculated upon, the drills, if the ground is very dry, may with advantage be well soaked with water before sowing, using soft rain or river water in preference to cold spring-water, that the temperature of the soil may not be lowered ; and for this purpose it is advisable to drill and water early in the morning, and to sow towards the afternoon, for, if the day be warm, the soil will have regained its former temperature. It is well also for this crop to mix guano and salt with the water, to the extent of a pound-weight of each to 25 gallons of liquid. The seed, also, may be steeped for six or eight hours in soft tepid water before sowing ; and if soot or flowers of sulphur be mixed in the water, both will adhere to the seed, and render it less palatable to birds. In drilling, as for carrots, the drill-rake

should be used for opening them equidistant, speedily, and of uniform depth ; and the drill sowing and covering machine (*see* section POTATO) will be found a great economiser of labour. The ground, after sowing, should be left quite open, and by no means scratched over with a rake, as if it were a border of mignonette in a highly-dressed parterre. The agriculturist rolls his turnip-ridges down after sowing, to break down the hard clods of earth, and render the process of singling more easily effected, as well as more completely to cover the seed in the drills. The gardener has seldom the same reason for doing this, as his soil is presumed to be sufficiently pulverised by previous working ; and it can only be where his soil is strong and lumpy, and, even then, when it is sufficiently dry that the roller may mellow down the clods, that he is justified in the operation. The evil of finely raking kitchen-garden ground is sufficiently obvious : it prevents the admission of heat and air to the roots or seeds ; in many cases renders it crusty and hard on the surface, so as to prevent the young plants breaking through it, and in fact completely stultifies every argument in favour of keeping the ground open and pervious to the elements. Many persist in raking garden ground from an idea of neatness and orderly appearance ; but the best appearance such ground can have is a total absence of weeds, and a loose, open, pervious surface. There are no garden grounds kept in higher order than the market-gardens round London, in many of which a rake is scarcely to be found, and seldom employed unless in breaking in the ground previous to planting or sowing—rarely otherwise. In ground subject to the disease called Anbury, or Finger-and-toes, which is occasioned by a small species of *Cynips* (*vide* paragraph *Diseases and insects*), the usual means may be adopted at sowing ; for, should they do no good, they can do no harm, and most of them will advantage the crop, as manures, sufficiently to repay the labour. These are, sowing the ground with soot, salt, guano, spirits of tar, lime, soap-boilers' waste, or any cheap alkaline substance : these are best spread over the ground before drilling, as that operation greatly favours their thorough amalgamation with the soil.

“The London market-gardeners sow principally the early stone or Dutch, it being in great demand in spring. Various ways of producing it are practised, such as growing it in frames; but the best plan is to raise it, like potatoes, in hooped beds—*i. e.*, in trenches, dug out and filled with 2 feet of hot dung. Sow in February; hoop and cover with straw, and expose the plants daily; the quality of the turnip depends much upon quick growth and plenty of moisture.”—CUTHILL. This practice, however suitable it may be to the climate of London, would be found of little avail in most parts of Scotland, where, to insure success, glass coverings day and night must be had recourse to. We may, at the same time, take this opportunity of stating that, high as the system of culinary cropping is, as carried on by the London market-gardeners, all this hooping and covering with straw, mats, &c., is neither profitable, nor up to the present state of horticultural science. Let them have pits miles in length if they will, 6 feet in width, supported on 10-inch piers, and sunk or elevated, below or above the surface, according to the dryness of the subsoil; and these not less than 4 feet in depth, with side walls of 10-inch brick-work, for durability and exclusion of cold, and covered with cheap glass. In spring, they could forward in these turnips, radishes, asparagus, lettuce, small salading, early cauliflower, early dwarf pease, French beans, &c.; while tomatos, which come in altogether to the market, could be spread over three or four months. In summer, cucumbers, melons, &c. could be produced; and in autumn, late cauliflower, full-grown lettuce, endive, &c. could be protected, thus producing three crops per annum, and at (after the first cost of erection, which would last ten or fifteen years) little more expense of working than the present antiquated process, and certainty substituted for uncertainty, and constant success for frequent failures. It is quite notorious that a lettuce salad cannot be procured in Covent Garden market, after October, equal to what is quite common in the Paris market all the winter; and asparagus, before New Year’s Day quite a novelty in London, is a common affair in Paris and Vienna by the 1st of December. Stable-manure, or heat produced by vegetable fermentation, must for long yet be the heating medium

employed by the London growers, on account of its cheapness and abundance, and the comparative scarcity and expense of fuel. The Glasgow and Edinburgh growers are differently circumstanced, where a load of stable-manure costs nearly as much as a load of coal. Were the demand equal, and could the same prices be obtained in the latter case as in the former, no doubt heating by combustion would be adopted by the northern growers. In these days of cheap timber and cheap glass, there is no reason why Mr Solomon of Covent Garden market should exhibit in Regent Street asparagus purchased in Paris on the 1st of December, better than is shown in Covent Garden market on the 1st of February; and far less reason is there why we should be supplied with early potatoes and pease from Spain, Portugal, Holland, or even Cornwall, when these could be produced by every grower round London quite as early, of much better quality, *being fresh*, and as cheap, were they only to cast aside their dependence on the identical means employed a century and a half ago, which a reference to the writers of that period will evidently show. In open-air productions they surpass all Britain; in the production of forced vegetables and fruit they are immeasurably behind.

To insure a speedy germination of the seed, care must be taken that it is not buried too deep: 1 inch may be taken as the maximum depth in garden soils; if placed deeper, vegetation is considerably retarded; and indeed, if too deeply buried, it may not vegetate at all, until brought nearer the surface by some future operation of digging, &c. Turnip-seed, if new, will germinate, and appear above the surface, in ordinary soils and situations, in the month of July, in about eight days; but older seed, which should assuredly be employed, will take from ten to twelve days; much of this, however, depends on the state of the weather.

The Swedish and Teltow turnips, as we have stated above, may be transplanted with every success. In gardens where the economy of ground is an object, it is well to sow both kinds in beds by themselves, in the broadcast manner, and, when the leaves are about from 3 to 4 inches in height, to transplant them to where they are to remain. By adopting this method, ground may be got cleared and prepared

for their reception, which might otherwise be in full perfection of crop at the period when these turnips should be sown. In lifting them, care should be taken that the roots are got up entire : the operation of lifting them will be facilitated if the seed-bed get a good soaking of water early in the morning of the day on which transplanting is to take place ; it will cause the roots to part more freely with the soil, and they, at the same time, will absorb such a portion of water as will greatly make up for the evaporation to which their leaves will be exposed before the spongiolets are in a condition to throw in a sufficient supply for the support of the plants. A dibble of sufficient length and thickness must be used, so that the root may be set in the hole in such a manner that its natural position may be maintained, and the soil gently pressed around it, but not in the way practised by many, of thrusting the dibble into the ground as soon as the root is set in the hole, in an oblique direction, and giving it a twist, with a view, as they say, of firming it at the bottom. Such a mode of proceeding is of all others the most likely to push the root out of its perpendicular position, if not to break it entirely.

Besides the advantage of economising space, by following the transplanting principle in the case of Swedish turnips, we have the opportunity of rejecting forked or apparently malformed roots ; and even another, and to us rather unexpected, advantage has occurred in Wigtonshire, as reported by Mr Stephens, in "The Book of the Farm," vol. ii. p. 82, and obtained by Mr A. Johnstone, "on transplanting swedes on land which he had not got ready for sowing them at the proper season. He sowed some seeds of Skirving's swedes in a bed in April 1847, and transplanted the plants from them as late as the 22d of June. From ten to twenty days afterwards, the transplanted plants running into flower, some of them were pulled up, and others cut over near the ground ; when, in about fourteen days afterwards, bulbs began to form, and new stems and leaves were put forth luxuriantly. He then cut over others that had flowered, and the same results followed. Finding the green leaves succulent, he caused them to be pulled as green food, and continued to do so during the season,

three times, never imagining that the bulbs would be of any value. Meanwhile, however, the bulbs enlarged until the end of October, when two were pulled up, and one weighed 18 lb. and the other 15 lb., with scanty stem and leaves, because the former ones had been cut down not long before." This appears so far to confirm the newly-started opinion that tubers and bulbs will increase in size after the leaves and stems have been removed from them.

"The question after such treatment of the bulbs" of the Swedish turnip "is, Are they deteriorated as food?" From an analysis made by Professor Johnston, it would appear they were not.

The Teltow may be set in rows 1 foot apart, and the plants 9 inches asunder in the row ; while the Swedish should have 18 inches between the rows, and 12 between the plants in the line.

Thick-sowing can only be sanctioned on the plea of affording sufficient food for the *Haltica nemorum* (the flea or beetle), the *Curculio contractus*, *Tenthredo* (or saw-fly), and other insect enemies, to satiate them during the period of their limited existence, and still leave a crop behind. Other means have been had recourse to, with more or less effect, such as that of mixing old and new seed in equal proportions, dividing the mixture, and steeping one half twenty-four hours in water ; although sown at the same time, four distinct brairds will be insured, one of which has, so far as our experience goes, a fair chance of escaping. It has often happened, when one-year and three-year old seed have been mixed and sown together, that the insect completely ate up the braird from the new seed, and had disappeared before the other had come above ground. Radish seed, which germinates so much sooner than the turnip seed, has been sown for a like purpose ; for it should be borne in mind that these insects prey alike upon all cruciferous plants. No better way exists of ridding the crop of such intruders than that recommended by Mr A. Gorrie many years ago, which is to dust the young plants with caustic lime in powder, and the simplest way of applying it is to put it into a thin canvass bag, and to shake it over the plants twice a-day, when their leaves are quite dry ; but this remedy, like most others, greatly depends on the quality of the medicine.

Lime which has been slacked and laid by for some time is of little avail; it should be brought direct every three or four days from the kiln. Nor should it be laid on in large quantities, more especially when the leaves are wet, else it forms an incrustation on them, and shuts up their pores of respiration, making in such cases the cure as bad as the disease. We have no dread whatever of the turnip flea so long as a lime-bag is at hand, and provided those intrusted with the operation will do as they are desired. Heavy rains also discomfit the insects, and, as a substitute, water let fall from the rose of a watering-pot held 3 or 4 feet above them will produce a like effect. All blanks which occur in the drills, from whatever cause they may emanate, should be speedily re-sown; but before doing so, fork up the soil in the patches, and drill and sow afresh; and to keep the crop as equal as possible, steep the seed to be sown twenty-four hours in tepid water to forward its germination.

*Subsequent cultivation.*—Keeping the ground thoroughly stirred by deep hoeing with the Vernon hoe, or the grubbers attached to the hoeing, sowing, and drilling machine, which will not only promote growth in the plants, but prevent the appearance of weeds, are the principal operations required, if we except the important duty of thinning the crop as it advances. The distances we have stated above. The operation of thinning should be performed by the turnip-hoe, fig. 64, which for this purpose should be kept clean, and as sharp as a knife. The 2-inch or 2½-inch hoe is the implement best suited for this purpose, and a dexterous person, accustomed to such an implement, will hoe triple the quantity with it that an old woman will do with a 7-inch tool, as recommended and used in the sister art. In very dry seasons, turnips, in all their stages of growth, are much improved by watering; it swells the bulbs out rapidly, and prevents their becoming hard, dry, and stringy, as well as running prematurely to seed. The first thinning by hoe should take place when the plants have made their first rough leaves—that is, those succeeding the radicle or cotyledon leaves, and at this time about 1 inch in breadth, if sown broadcast in beds, which the two earliest

crops may be, and thinned to the distance of 2 inches apart, and in course of a week to the ultimate distance of 4 inches apart. Those of later crops in rows, when of the same size, should be thinned first to 3 inches, and in course of eight or ten days to 6 inches apart in the lines. This, again, depends on the size of the varieties, as well as the size at which they are to be drawn for use; so that in some cases the 3-inch distance may be sufficient, afterwards drawing every alternate one for consumption. In small gardens, where young turnips are in demand, this is sufficiently expedient; but otherwise it is better to give the second thinning, and to depend, as already said, for supply upon a small crop sown on purpose. Half that distance will be sufficient for the French or Teltow turnip, as neither its roots or foliage are large.

*Soil and manure.*—A turnip soil is almost a synonymous term with a light sandy or light loamy soil, for in such they succeed better than in stronger and more tenacious ground. In the former the crop will be much earlier, more easily managed, and the roots of better flavoured quality. In strong soils the crop is much later, more likely to shoot up to seed, particularly early in the season, and the roots are always deficient in flavour. New soils produce the best turnips, but all should be in an enriched state, either naturally or artificially. The richest manures may be applied, and, as has been shown practically in the case of one of the most powerful (pigeons' dung), disease as well as insects have been greatly kept under by it.

The turnip tribe differs from the potato in two most important points. First, The quantity of water they respectively contain. In the potato this forms three-fourths, but in the turnip nine-tenths, of the whole weight, when taken from the ground; or they consist of—

	Potato.	Turnip.
Water,	75	91
Dry nutritive matter,	25	9
	100	100

Second, In the presence of starch in the potato, while the turnip contains in its stead a substance called pectose, or pectic acid, which contains more oxygen than starch, but serves the same purpose in the nutrition of animals. "In fleshy fruits, such as the plum, peach, apricot, apple, pear, &c., and in the bulbs or roots of the turnip, the carrot, the parsnip, &c., there exists no starch, but in its stead pectose, or pectic acid.

This substance is nearly as nutritious as starch, and serves the same purposes when eaten. It contains, however, less hydrogen and more oxygen than starch does, and changes more readily into other substances, both in the plant and in the stomach."—J. F. W. JOHNSTON, in *Agricultural Chemistry and Geology*, p. 46, 325.

*Forcing*.—This is seldom attempted in this country, excepting in gardens of the highest order. It forms an important part in Russian and German gardening, where otherwise it would be late in the spring before they could be obtained from the open ground. Slight beds of leaves, or of leaves and stable-yard litter combined, about 3 feet in height, are, for the purpose of forwarding an early crop in some British gardens, made up in February; and when the heat has risen to the surface, they are earthed over, to the depth of 3 or 4 inches, with light rich soil. The seed is sown broadcast, and covered to the depth of half an inch, choosing the true early white Dutch, or early six-weeks, as coming soonest into use. Air must be freely admitted on all favourable occasions, and, in severe weather, the glasses covered during the night. When the plants have shown their first rough leaves, about the size of a shilling, they should be thinned to the distance of 3 inches apart; and when pulling commences, which will be when they have attained the size of a pigeon's egg, a regular system of thinning should take place by removing the largest first. Slight watering will be required, and that should be applied at from 60° to 80° of heat, with a view of adding to the warmth of the soil rather than abstracting heat from it. The turnip does not, however, require a temperature of more than from 50° to 60°.

*Taking the crop, and subsequent preservation*.—From the time the bulbs are of the size of a pigeon's egg, until they attain a diameter of about 4 inches, they are fit for use, and are drawn progressively. When gathered and removed to the vegetable-house, they should be clean washed, the tops cut off close to the crown, and the tail-root close to the bottom of the bulb, in which state they are ready for the kitchen. Those that are intended for winter use may for the most part, in favourable situations, be left in the ground, securing a few for supply in the event of frost, which should be stored by in the root-cellar. In cold, wet, and uncongenial localities, it is quite necessary that

the crop be taken up and stored for winter and spring use, after the manner of potatoes (*which see*). To prepare them for this a dry day should be chosen, and also one when the ground is dry to pull up the roots, to divest them of their tops and tails, cutting both off close to the bulb. Some, however, object to this, and leave about an inch of the tops, and the whole tail or root entire, alleging that the sap is better retained in the bulb when these curtailments are not made.

*Approved sorts and their qualities*.—Garden turnips may be divided into two classes, the yellow and white bulbed sorts. The white varieties are most esteemed for table use in England; while the yellow, particularly during winter, hold the same rank in Scotland. French cooks rarely use the yellow sorts; they are, therefore, less generally grown in gardens, being considered less mild in flavour than the white ones, while many prefer them on this very account.

*Yellow Malta*.—This is a beautiful small-bulbed variety, from 1½ to 2 inches in diameter, of great symmetry in form, slightly flattened above, somewhat concave on the under side towards the tap root, which, as well as the neck, is remarkably small; skin very smooth, of a bright orange-yellow colour; leaves also small, admitting of their standing close on the ground. This is the very best, for summer use, of all the yellows, and, from its fine small size and form, is usually dressed whole. It is rather tender for winter use. Known also as the Maltese golden.

*Robertson's golden stone*.—A comparatively new and excellent variety, brought under our notice three years ago by Mr Robertson, Paisley. In shape it is nearly globular, and of a deep orange-yellow colour throughout, very slightly tinged with green on the top, often none; the best yellow for autumn and winter use, as it keeps well, and is exceedingly hardy. It attains a pretty large size.

*Finland*.—Is thus described in Messrs Peter Lawson and Sons' "Vegetable Products of Scotland," p. 13, div. iii.: "This is a beautiful little turnip, of a bright yellow throughout, even to the neck, somewhat similar to a small firm yellow Malta, but differing in the fine colour, and having the under part of the bulb singularly depressed, from which issues a small mouse-tail-like root. It is also somewhat earlier than the yellow Malta." We believe it is also hardier. Our knowledge of it extends to having seen it growing in Messrs Lawsons' experimental grounds, and from its appearance we would judge it, along with the yellow Malta, well suited to small gardens.

*Yellow globe*.—Bulbs of medium size, globular, and always nearly under the surface of the ground; top greenish; leaves rather small and spreading. This is a most excellent turnip for garden culture, and, with Robertson's golden stone, the two most valuable where the larger-sized garden turnips are required. To these may be added the old and long-cultivated yellow Dutch and

yellow stone, the last probably the type from which the third has been obtained. The yellow Preston, or Liverpool Preston, and the yellow Altringham, are both much grown in the north-west of England. We consider them good, but coarser in growth and delicacy of fibre than those we have described above.)

*White Dutch.*—One of the oldest in cultivation, and most esteemed for early crops; round and much flattened; leaves medium-sized. While young, it is juicy and of excellent flavour, but apt to become spongy and dry when too old, particularly in dry seasons. In perfection when from  $1\frac{1}{2}$  to  $2\frac{1}{2}$  inches in diameter; after that size it is next to useless. It will not keep either in the ground or in pits through the winter, compared with the following.

*White stone.*—Shape of the bulb much more globular than the last, and firmer in texture and rather stronger in foliage. According to the Messrs Lawsons' description in "Vegetable Products of Scotland," div. iii. p. 14, "it is not, however, so well adapted for early spring-sowing, being more apt to run to seed, and has acquired the name of early from the circumstance of its arriving soon at maturity when sown at a late period of the season. A carefully selected and improved variety of this is known in some parts of England by the name of mouse-tail turnip; and, in addition to this, some seed-catalogues present us with the names of red-topped, mouse-tailed, and we think we may add the name of snowball also. It is sometimes also called the white garden stone.

*Early six-weeks.*—Bulbs of an irregular globular shape, produced for the most part above the surface of the ground. It arrives soon at perfection—hence the name; a good-tasted turnip, soft, and not adapted for winter use. We sow it as an intermediate crop during summer, for the supply of young tender turnips. It is known as the autumn stubble, early dwarf, and early ball.

*Stone globe.*—A well-shaped globular bulb, produced generally almost under the surface, which circumstance, together with its hardness, renders it the best winter-keeping sort. Its leaves are stronger than any of the above, and of a much darker colour.

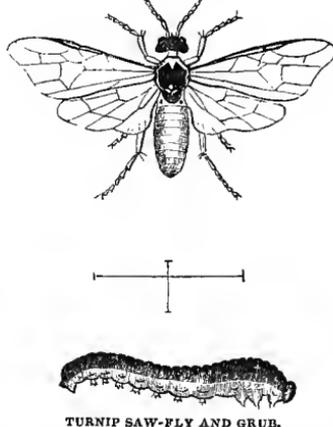

*The French turnip or navet.*—Of an oblong fusiform shape, from 3 to 6 inches in length, about 1 inch in diameter at the top; dull, semi-transparent, whitish colour; possessed of peculiar qualities, for which it is esteemed in French cookery. Vide *Uses*, p. 184.

*Swedish turnips*, we have remarked, p. 183, are grown in gardens, particularly in cold and elevated places, with a view to afford a supply during spring, when other sorts are consumed; as also for the purpose of placing the bulbs in a warm dark cellar in November, and successively in small lots till February, to produce a substitute for sea-kale, or to make an additional dish in resemblance of it. For the former purpose, a rather scarce and not often grown variety is the best—namely, Thorpland globe swede—on account of the symmetry of its form, which is of a beautiful globe shape, without the least appearance of neck, and also on account of its being smaller in size than any other variety

in this section. We are aware that the prevailing opinion is that the larger the swede the more tender the fibre is, and altogether better for the purposes for which they are generally grown. This may in field culture be quite correct; but we have found this variety superior, in our estimation, for culinary purposes, when grown in garden soil, and not sown till the beginning of July.

*Diseases and insects.*—The turnip is attacked by a multitude of insect enemies, of which *Athalia centifolia* of some, *A. spinarum* of others (the turnip saw-fly, black caterpillar, blacks,

Fig. 65.

TURNIP SAW-FLY AND GRUB.

canker, black palmer, nigger or black grub), fig. 65, is one of the worst. It is called saw-fly, from the use and appearance of the instrument with which it deposits its eggs. This is placed at the extremity of the abdomen of the female, on the under side, and is so constructed that it combines the properties of a saw and auger. The following excellent description is given by Mr Curtis, in "British Entomology," vol. xii. folio 617, as quoted by Mr Stephens in the "Book of the Farm:"—"Head wider than long; deep black, with three ocelli in the centre; eyes oval; antennæ black above, and for the most part dull yellow beneath; labrum and pulpi light yellow; thorax black above, with a triangular space in front; the scutellum, and a spot behind it, reddish orange; the collar, which is rather long and slender, black on the sides and yellow in the middle; abdomen rather short, entirely orange yellow, inclining to red, with a small black spot on each side of the first segment; legs likewise orange yellow; the tarsi paler, approaching to whitish; the tip of the tibiæ, and of each of the tarsal joints, black; the tibiæ, with two spines at the apex and the joints of the tarsus, each with a very slender lobe beneath; extremity of the ovipositor black; wings yellowish at the base; the costa and stigma black. Length, 3 to  $3\frac{1}{2}$  lines, exclusive of the antennæ. Antennæ short and somewhat club-shaped, nine or ten jointed in the male, but generally with the appearance of eleven joints in the female; the radical joint slightly thickened at the extremity; the second shorter and oval; the third as

long, or longer, than any two of the other joints taken together; the remainder decreasing somewhat in length to the terminal one, which is large and oval. The flies, which appear in the early part of summer, and deposit their eggs on the young turnip plants, have probably survived the winter under ground in the pupa state, enveloped in their cocoon. Emerging from them, as soon as the milder weather is confirmed, in their winged state, the females immediately lay their eggs, after which they very soon die. The eggs appear, for the most part, to be placed round the outer margin of the rough leaves. In favourable weather they are hatched in a very short time, and the young larvæ immediately commence their attack on the plant. At first these larvæ are of a deep black colour, and, of course, small size; but they grow rapidly, and in course of a few weeks attain their full dimensions. In the course of their growth they change their skin several times, and most of their moultings are attended with a slight change in their colour. After casting their last skin, they are of a dark lead or slate-grey colour, paler beneath." Mr Curtis states that they are sometimes *green*, a colour which we never saw them assume, for in general they are not liable to much variation in this respect. Like most of the other larvæ of their tribe, when touched or in any way disturbed, they coil themselves up and remain motionless. When full grown, the larvæ cease to eat, and allow themselves to drop from the plant that nourished them to the ground, in which they usually bury themselves; or they take shelter among rotten leaves, moss, &c. When examined after a short time, they are found to be completely enclosed in a cocoon composed of two distinct layers of silk. The inner layer is of a fine satin lustre; and when the cocoon is opened, it appears as if it had been washed with a solution of silver. When the fly is fully matured, it makes its exit by gnawing with its mandibles a hole in one end. The larvæ are known in different parts of the country by the names we have given above. They often destroy the crop entirely, and at other times very seriously injure it, destroying the leaves either wholly or in part. Some have asserted that they do not attack the Swedish turnip; but this opinion is not borne out by facts: nevertheless, they are less severe upon them than on the other varieties. Many remedies have been recommended for lessening their numbers: as to complete annihilation, that is only a thing to be wished for, without much expectation of its being realised.

Brushing them off the leaves, by drawing a light broom over the plants, has been recommended. This recommendation is offered on the presumption that they are unable to crawl on the ground and recover their position; but experience has shown us that they have the power of locomotion sufficiently strong to enable them to ascend again when brushed off. Besides, as they are produced in generations following each other in succession, from August till near November, a frequent repetition of brushing would be necessary during that period. Birds greatly assist us in reducing their numbers, and heavy showers of rain are of great service, while it

points out to us a remedy in applying water from the rose of a watering-pot held somewhat elevated, that the force of the falling water may be the greater. A fire-engine, or a powerful garden-engine, may be brought to play upon them with great advantage; and, if wrought upon the walks, a boy may be employed to direct the nozzle, so that the water may not be unnecessarily wasted on the spaces between the drills. Lime-water is better than pure water; the trouble of applying both is the same, and the difference in expense next to nothing. The caustic property of the lime-water will destroy them in vast numbers; for falling upon them while young, and particularly when they have newly shed their skin, it is instantaneously fatal to them. Dusting the leaves with powdered hot lime once a day is very destructive to them, acting upon their tender bodies even with more effect than when applied in a liquid form. Catching the perfect fly before it has laid its eggs is the next most effectual plan; and this can readily be done by the aid of an entomologist's net, for they are slow flyers, and do not take long flights at a time. Each fly caught would prevent the coming into existence of from 250 to 300 caterpillars. Hand-picking the caterpillars would be very wholesome advice to give a Chinaman; but where labour is high, and large breadths have to be gone over, very unsuitable to the British cultivator. Old ducks and old fowls, as well as troops of young ones—remedies recommended by most writers upon rural affairs for more than a century—in most cases verify the old saying, "The cure is as bad as the disease."

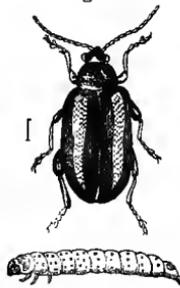

*Ceutorhynchus contractus*, the turnip-weevil, closely resembling the *Curculio pleurostigma*, fig. 47, is often found feeding upon young turnip leaves in company with *Haltica nemorum*, the turnip flea-beetle. It is a small insect, scarcely 1 line in length, of a uniform black colour, slightly tinted with metallic blue on the elytra, the latter with punctured lines.

*Haltica nemorum*.—The turnip flea-beetle, fig. 66, is thus described by Mr Stephens in

"The Book of the Farm," vol. ii. p. 73: "The insect which first infests the turnip plant, and attacks its seed-leaves, is the turnip flea-beetle, *Haltica nemorum*, fig. 66, usually, though improperly, designated the turnip-fly, which is a very different sort of insect. The flea-beetle is a coleopterous or hard-shelled insect, capable of either penetrating the ground or bearing a considerable pressure." "It is a small insect," says Mr Duncan, "scarcely one-eighth of an inch in

length. It is smooth, shining, and of a brassy black colour, with a slight tinge of green, particularly on the wing-cases; the antennæ black, with the second and third joints, and the apex of the first, of a pale colour. The thorax

Fig. 66.

TURNIP FLEA-BEETLE AND GRUB.

is convex above, and pretty deeply punctured; the wing-cases are much wider than the thorax, likewise thickly and irregularly punctured, each of them with a pale-yellow or slightly sulphur-coloured stripe running along the middle, curved inwards posteriorly, and not reaching quite to the extremity; the under side of the body and thighs black; all the tibiae and tarsi of a pale hue. This little insect feeds on the turnip, which it attacks both in its perfect and larva states. When the plants have acquired some degree of strength, and the foliage is considerably developed, the injury done by it is insignificant; but, unfortunately, its favourite food is the young plant, just as it is beginning to unfold its cotyledon leaves. These it consumes with the utmost avidity, both as a larva and a full-grown insect; and where it abounds, the field is often wholly stripped of its crop in a very short time. Indeed, their powers of mastication are surprising for creatures of so small a size. They are found to attack the turnip plants as soon as the latter make their appearance; and one of the difficult points to determine is, how they are produced so speedily and so opportunely. In regard to the turnip saw-fly and lepidopterous insects the process is obvious, the eggs being laid upon the plant by the parent fly, and the larvæ evolved more or less speedily, but after the lapse of some considerable time. The appearance of the plant and insect being in the present case almost simultaneous, it has been thought difficult to conceive how the same process should be gone through.—*Quarterly Journal of Agriculture*, vol. viii. p. 353. Various conjectures have been formed to account for the early appearance of this insect on the turnip plant. "But these conjectures," continues Mr Duncan, "may now be referred to merely as matters connected with the past history of this insect, and as showing the difficulty that has been experienced in tracing it throughout its different forms and changes. This, however, has been recently done by Mr H. Le Keux, and we are no longer in doubt as to the points alluded to. This observer found that the sexes pair from April to September, during which period the eggs are deposited on the under side of the rough leaves of the turnip. The female insect does not apparently lay above one egg daily; in a week ten pair are found to lay only forty-three eggs. These eggs are very minute, smooth, and partaking of the colour of the leaf. They are hatched in ten days; the maggots (fig. 66) are an eighth of an inch long, pale, fleshy, and cylindrical, with six pectoral feet; the eyes dark, and a dark patch on the first and last segments of the body; they immediately eat through the lower skin or cuticle of the leaf, and form winding burrows among the pulp, upon which they feed. The thickness of the leaf is sufficient to afford them ample scope for this, and they may be seen at work in their galleries by holding the leaf up to the light. These maggots or larvæ are full fed in sixteen days, when they bury themselves in the earth not quite 2 inches under the surface, selecting a spot near the bulb, where the turnip leaves protect them from wet and drought;

they enter upon their chrysalis state in the earth, and the beetle emerges in about a fortnight. About thirty days carry the insect through all its different stages, and of these ten are passed in the egg state, six as a maggot, and fourteen in the chrysalis. There appear to be five or six broods in the season."—*Transactions of the Entomological Society of London*, vol. ii. p. 24.

On this subject Mr Stephens, in "Book of the Farm," vol. ii. p. 74, makes the following sensible remarks on the economy of such insects, and also on the remedial measures that might be adopted for their suppression: "In the case of those insects which feed on the foliage of plants in their larva state, and afterwards derive their aliment from other substances, the general law seems to be that a much longer duration is assigned to the larva than to the perfect insect; and it may be that this is not observed in regard to such as always consume vegetables, because in either of these conditions they serve the same purpose in the economy of nature, to which the prolonged existence of the larva bears reference in the other instance. Parallel examples are of frequent occurrence amongst insects. Unless the eggs of the common flesh-fly were hatched with extreme rapidity, the larvæ, when they appear, would neither obtain their food in perfection, nor fulfil the useful purposes for which they are now subservient. The remedies against the attacks of this insect," Mr Stephens fears, "are of a hopeless character; at least, it is better to prevent their appearance than to wage war against them when they do appear, as, even in the efforts to effect their destruction, the cultivator is the chief sufferer." The preventive measures, Mr Stephens thinks, are to keep the ground clear of weeds, particularly those of the cruciferous order, which are especial favourites with this beetle, to sow in drills instead of broadcast, "and to sow the seed thick and of the same age, for it is found the more rapidly the plants grow at first, they are the less often attacked; to put the seed for some time before it is sown amongst flowers of sulphur, and sow the sulphur amongst it." This latter is, we know from several years' experience, a very great check to this insect, and, indeed, to all others that attack the Cruciferae. We have little faith in brushing the insects off the plants, as they have the means of taking possession of them very shortly afterwards: dusting with hot lime, and watering with lime-water, applying it with force, are the best remedies we have tried. For years we held a strong opinion on the advantages of sowing turnip-seed of several ages, believing that the insect would seize upon and devour the crop which first germinated, and which would be from the seed of the previous season's growth; and that by the time the older seeds had germinated, the brood would have changed into another state; and such, no doubt, might be the case, if the insects were all produced at once, or from one hatching of the eggs. Subsequent observation, however, has convinced us that this is not the case, but that brood after brood is hatched; and several germinations of

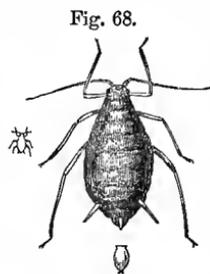

seed would only be presenting each brood with a supply of food in about as regular a succession as they themselves are produced.

Burning the surface of the land is beneficial where it can be carried into effect, as by that means the chrysalides will be destroyed; and an equally certain way is to trench the ground deep. Indeed, the destruction of insects alone, were no other benefit to arise from trenching, would of itself be a sufficient recompense for the labour incurred. Sowing the surface of the soil with gas-lime two or three mornings after the seed has been sown, has been recommended on account of the disagreeable smell being so offensive to the insect as to drive it away. Spirits of tar, in the absence of gas-lime, would have the same effect.

Charcoal dust may also be sprinkled over the plants when they are either wet with rain or dew; and in small gardens the watering-pot may be had recourse to to wet the foliage, should neither rain nor dew fall. A temporary light-frame, stuck full of green alder-branches, and drawn over the crop, will discompose the enemy, and a stripe of light woollen cloth, 6 inches in width, and covered with bird-lime, tar, or any equally adhesive matter, and nailed to a wooden axle attached to two 12-inch wheels, and drawn over the crop, will greatly lessen their numbers, as the cloth brushing over the tops of the young plants will disturb the fleas, and cause them to leap from the leaves and become attached to the cloth; and, on account of its adhesiveness, they will be unable to disengage themselves. This operation, performed about twice a day, will in general secure a crop. In small gardens a piece of cloth so covered and attached to a handle like a small flag, and drawn over the plants backwards and forwards, will have the desired effect.

*Aphis rapae* Curtis, *A. vastator* Smee, *A. dianthi* Schrank, figs. 67 and 68, is thus well de-

quished from the other species by its long tubes and small apical cells of the wings. The cross

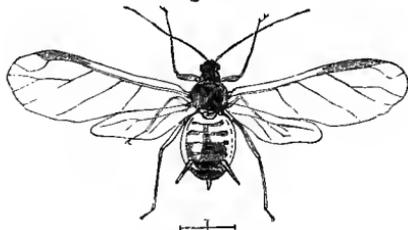

TURNIP APHIS, FEMALE.

lines below represent the natural size of the body and of the expanse of the wings. Fig. 68 is the female of the same species magnified. It is bright green, shagreened; horns fuscous, except at the base; eyes, tips of shanks, and feet black. The small figure on the left represents the aphid of the natural size; and the figure below represents one of the natural size just excluded."

Ruricola, in "Gardeners' Chronicle," 1847, p. 21, of this insect says: "It is to be hoped that the species of the aphides will be determined, that it may be settled whether those found on the turnip (of which there are three species), the potato, the spinach, &c., be identical or different. Another object will be to ascertain if the aphides actually feed upon the leaves and shoots of the later plants, and breed there." Of the *Aphis rapae*, he continues: "I do not remember ever observing it before midsummer. In July it becomes abundant, and in favourable seasons continues increasing until the end of October, or later. The first are hatched from eggs, and it is said are all females; these bring forth young until the autumn, when males are produced, as well as females furnished with wings. These lay eggs, which remain through the winter."

The injury done by the various species of aphides, or plant-lice, is incalculable, as may be well supposed when we consider that there is not a plant that would seem exempt from their attacks in one way or other; and it would also appear, from the investigations of some of our most eminent entomologists, that almost every plant has an aphid natural to it, and upon which it is designed to feed. Ruricola, in "Gardeners' Chronicle," 1842, p. 3, of this extensive genus thus speaks: "There is no family of insects which deviates in its habits more from the general laws of nature than the aphides; for whilst it is an almost universal rule that this class of animals should progress through the various transformations of egg, larva, pupa, and imago, the aphides have the power of evading three of these states by the faculty they possess of producing young; for, influenced by natural causes, they are both viviparous and oviparous—bringing forth young at mild seasons, when the temperature is not injurious to their tender offspring, and laying eggs in autumn, which are better calculated to resist the cold of winter. But this is not the most curious anomaly in their history, for a succession of young aphides can be produced without the presence of the male insects. For instance, as soon as an aphid is born, if it be taken away and placed upon a plant, under a glass, where nothing can possibly gain access to it, it will, notwithstanding, produce young; one of which,

Fig. 67.

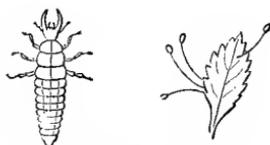

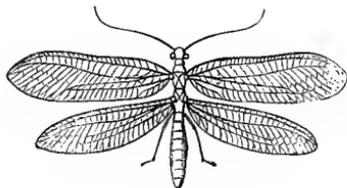

TURNIP APHIS, MALE.

scribed by Mr Stephens, in the "Book of the Farm," vol. ii. p. 77: "Fig. 67 represents the winged male of the common turnip plant-louse, *Aphis rapae*, magnified. Its characters are ochraceous; horns moderately long, setaceous; two first joints black, third ochraceous at the base; head blackish; collar ochraceous and brown; disc of shining black; abdomen greenish; wings iridescent; the nervures light brown; tips of the thighs, shanks, feet, and claws black. Abundant beneath the leaves of the common turnip the whole of July, &c. It is at once distin-

being also removed, and treated with the same care, will possess the same prolific faculty." Their power of reproduction, as observed by Bonnet and Reaumer, is such that the countless myriads of them which appear in our fields and gardens yearly can be accounted for without our having recourse to miraculous causes. "With such an inexhaustible power of fecundity, it is fortunate for man that no insects are subject to the attacks of such a variety of enemies. 1st, There are the lady-birds (*Coccinella*—figs. 14 and 15), which feed upon the aphides both in their larvæ and perfect states; 2dly, The aphidivorous Syrphidæ, the maggots of which are exceedingly useful in diminishing the number of the plant-lice. Then there are the Hemerobii; or golden-eyes, whose larvæ are called Aphis-lions (fig. 69), a ferocious family nearly related to the ant-lions. Another set of insects are parasitic, and deposit minute eggs in the old aphides, which then change to dull ochreous, horny objects, sticking to the leaves on which they had fed, frequently exhibiting a hole in their sides, from where the parasitic little ichneumon called Aphidius had issued." The earwig and ant wage constant war against them, and soft-billed birds work wonderful destruction amongst them; and to these we may add, as valuable to man—

The *Aphis-lion*, fig. 69, of which there are numerous species. They belong to the family

Fig. 69.

APHIS-LION, GRUB, AND EGGS.

Hemerobiidæ and order Neuroptera. The preservation of this family should be sedulously cared for, as they are bred, live amongst, and feed upon the plant-eating species of aphides, and are of the greatest importance to man. The aphis-lion makes its appearance in May, and may be observed walking about upon the leaves of plants, resembling more in appearance a small mass of cottony-like matter than a living insect. This covering is composed of the fragments of the skins of the aphides it has destroyed, and which, by a peculiar power invested in its jaws, as soon as it has sucked the vitals out of its prey, it throws upon its back, until, by repeated additions, it at last assumes the form of a

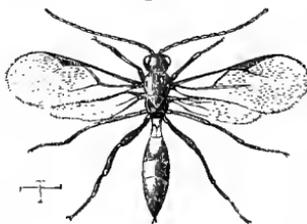

large semi-globular mass, probably as a means of hiding it from its own peculiar enemies, or more probably as a covering of protection to its soft and fleshy body. When the larva is fully grown, it spins a cottony cocoon of a globular form, within which it is transformed into a short inactive pupa. Its duration in the pupa state varies with the season of the year: it, however, remains in this state throughout the winter, the fly being produced in the early part of summer. The flies are generally abroad in the evening, remaining quiet through the day; they are by no means active on the wing. On being touched they give out a most disagreeable odour. The females deposit their eggs on the leaves of plants, especially such as are infested with aphides, attaching them to the leaf by a long slender arm or stalk, of a whitish colour—the eggs, when so placed, having somewhat the appearance of minute fungi. This stalk of attachment is composed of a glutinous matter the female discharges at the time of laying the egg, and this matter, hardening by exposure to the air, maintains the egg in a firm position. The insects, as soon as they are hatched, finding themselves in the midst of masses of aphides, commence warfare at once; and, as we have observed above, as the slaughter goes on, the skins, or fragments of them, are transferred to the back of the aphis-lion, until it becomes clothed as we have described.

And amongst parasitic insects which aid in the reduction of the aphides, may be instanced the

*Aphidius avenæ*.—This little ichneumon fly deposits its eggs in the apterous female aphides, and by this means reduces their numbers exceedingly. It is black and shining; horns long, and in the male having twenty joints: the body is brown, narrowing towards the base, which is rough and ochreous, as is also the margin and a patch on the back; legs rusty; hips and thighs, excepting the first pair, pitchy; feet blackish; upper wings having a large smoky stigma, and a large central cell, the posterior ones entirely wanting.

*Aphidius rapæ*, fig. 70.—Very similar in appearance and habits to the last; the

Fig. 70.

APHIDIUS RAPÆ.

however, a shorter, and only fourteen-jointed; the underside of the base and the mouth ochreous; stigma of upper wings smoky ochre; legs bright

ochreous, variegated with dark brown, and rusty. *Phytomyza nigricornis* (the black-horned leaf-miner), fig. 11, often attacks turnip crops. They operate by feeding upon the parenchyma of the leaves, in which they form long irregular galleries on the inside of the lower cuticle; they are

not visible on the upper side of the leaf. They often attack plants in greenhouses. The only way we know of is to pick off the leaves as soon as the insect appears to have attacked them, and to burn them. The larvæ of this insect are devoured in vast numbers by the *Ceraphron niger* and *Microgaster virides*.

*Noctua exclamatoris* and *N. segetum* (the heart and dart moth, fig. 71, and common dart-moth, fig.

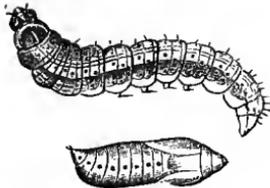

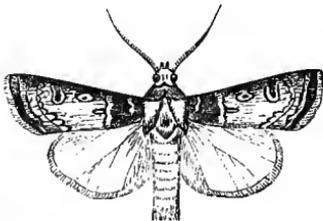

Fig. 71.

HEART AND DART MOTH AND CATERPILLAR.  
Natural size.

72). These insects appear to be either increasing of late years, or more probably their economy is now better understood than formerly. They

Fig. 72.

COMMON DART-MOTH, CATERPILLAR, AND CHRYSALIS.  
Natural size.

are of the class called surface caterpillars, or surface grubs, and are exceedingly destructive to various crops, particularly to turnips, potatoes, and mangold-wurzel. They commence hostilities upon the turnip in July, by eating off the crowns. They afterwards attack the bulbs, and render them unfit for use. In June they attack the mangold-wurzel by eating off the roots immediately under the surface of the ground, and they attack the potato when just

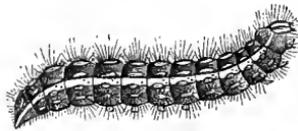

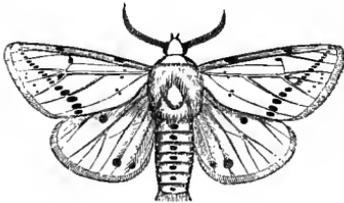

pushing above ground. They seem to feed by night, and towards morning carry away portions of the leaves, which they drag into holes, so that they may feast upon them at leisure and in safety. Like rabbits, they seem to take a pleasure in cutting over the tops from mere wanton mischief, as they have been detected decapitating plant after plant, without waiting to eat the same.

"Where the eggs of *N. exclamatoris* are laid has not been recorded; but it is stated that the moth of *N. segetum* deposits hers in the earth. The caterpillar of the former is somewhat cylindrical, but a little depressed above, having six pectoral, eight abdominal, and two anal feet. It is of a dull lilac colour, with a broad pale strip down the back, the margins of which form a darker line along each side, and there is a double dorsal line extending the whole length. The head is horny and brown; the minute eyes, and two curved lines, as well as the jaws, are black. The first thoracic segment is rather horny and dotted; the following segments have four little tubercles on each, producing hairs, as well as similar ones on the sides. The stigma is black. When full fed, it is an inch and a half in length, and hurries itself, forming an oval cell of the earth, in which it changes to a shining rust-coloured chrysalis, to pass the winter in; and the following June, or perhaps earlier, the moth hatches." The moth "is of a clay colour, the wings reposing horizontally; the horns are like bristles, but slightly pectinated in the males; the tongue is long; on the front of the thorax is a transverse dark patch; on the upper wings there are two waved lines near the base; to the second is attached a long, longitudinal, deep-brown streak; above it is a spot varying in size and form, and beyond it a large kidney-shaped one; then follows a transverse, pale, waved line; and near the cilia is a more irregular one. The under wings are white, the upper margin and nervures brown; but in the female the wings are entirely dark brown; their expanse is 1½ inch. The caterpillar of *N. segetum*" (or *Agrotis segetum* of Curtis) "is more cylindrical than the foregoing species; the sides are greener, and there are three black dots on the stigma." An excellent description of it will be found in the "Royal Agric. Journ.," vol. iv. p. 106. Ruricola, in "Gardeners' Chron.," 1844, p. 619, from whose excellent paper the substance of the above is taken, suggests, as remedies, salt-water, lime-water, and an infusion of tobacco, as being distasteful to these grubs, and also soot applied to the surface early in the year, and laid on an inch in thickness. "One lb. of soap, dissolved in 16 gallons of soft water, and applied warm to the infested ground, especially round the roots, the surface caterpillars will dart out of their burrows, and may thus be readily collected; but no time must be lost, as they will retire under ground as soon as its effects have subsided." The use of hot water has been too little hitherto understood in the destruction of insects. It may be applied at nearly the boiling point to most plants without injury to them, but with manifest effect upon insects, particularly grubs, whose skins are thin

and tender. We should not be surprised to see, ere long, a hot-water apparatus, somewhat similar to Mr Fleming's excellent machine for destroying weeds in walks, in use in every garden for the destruction of insects alone.

*Bombyx tubricipeda* (Linn.), the spotted buff-moth, fig. 73, is particularly destructive: no plant

Fig. 73.

SPOTTED BUFF-MOTH AND CATERPILLAR.  
Natural size.

seems to come amiss to it; it feeds on the turnip, horse-radish, carrot, scarlet-runner, and even mint does not escape its ravages. In the months of May and June they are observed in pairs on walls, plants, &c., when they should be destroyed. It is of a pale ochre or buff colour; antennæ black, bipectinate in the male; the eyes, feelers, and legs black, with the exception of the thighs, which are orange; tarsi and hinder tibia buff; body buff; the upper wings have one or more dots, with two black spots upon the margin; it is, however, very variable in its markings, varying from whitish buff to deep ochre, with large black spots. The eggs, which the female deposits on the leaves of plants, are whitish, round, and smooth. The caterpillars, when first hatched, are of a yellowish white, with very few long hairs. When of full size, they are about an inch and a half long; they are then of a dark green, with a white line down each side. The stigmata white, and covered with reddish-brown hairs. It has six sharp-pointed pectoral feet, eight on the abdomen, and two hind ones, of a more fleshy nature.

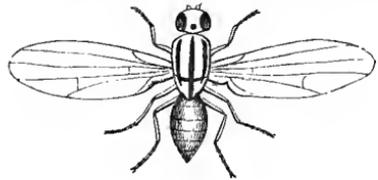

*Aphis brassicæ* (figs. 42, 43), the *Aphis florirapæ* of some entomologists, is also destructive to turnip crops, and indeed to most plants of the same natural order.

*Aphis dubia* (the black-spotted turnip-leaf plant-louse) is often found in company with *A. rapæ* on the under sides of the leaves of turnips. Both these species resemble each other closely, only in *A. dubia* the colour is a dull green, shagreened; horns dusky at their extremities, as are also the tops of the thighs, shanks, and feet; the eyes and ocelli are black, as are two patches on the collar, and several transverse broken strips along the back.

*Drosophila flava* (the yellow turnip leaf-miner), fig. 74, is a minute fly, which lays its eggs on the

leaves. "The maggots produced from them eat into the pulp, and form large whitish blisters on

Fig. 74.

YELLOW-TURNIP LEAF-MINER.

the upper side. When full-grown, they are pale green, and change to chestnut-coloured pupæ, with two small horns at the head, and from these the flies are produced. These are ochreous, with black hairs, and two little feathered horns. The eyes are black; there are three ochreous strips down the trunk; the six legs and two balancers are yellowish and downy; the two wings are large and iridescent. The larvæ of this insect are destroyed by two little parasitic hymenopterous flies, the *Ceraphron niger* and the *Microgaster virides*.

*Ceutorhynchus pleurostigma* (the turnip gall-weevil) effects the disfiguration, at least, of the turnip bulb, by "the female piercing a hole in the rind of the turnip with her proboscis, and depositing an egg in it; and the young maggot, which is fat and whitish, often of a bright flesh-colour, lives on the substance of the bulb," causing those excrescences which are so often observed on turnips, particularly in dry seasons. The general appearance of this insect is that of a small black seed, and, excepting in colour, it resembles the turnip-seed weevil, which latter is of a grey colour.

*Triphaena pronuba* (the great yellow underwing), fig. 75, in its caterpillar state, is one of

Fig. 75.

GREAT YELLOW UNDERWING MOTH, CATERPILLAR,  
AND CHRYSALIS. Natural size.

those enemies known as surface-grubs, and often attack the turnip-bulb, particularly in gardens where the plants are nearly full grown. These have also their natural enemies in the genus *Cryptops*—Scolopendra of some (the centipedes), fig. 76. If the value of these were rightly understood, the vulgar prejudice against them would be removed. They are all of the carnivorous or flesh-eating section, and devour immense

Fig. 76.

GARDEN CENTIPEDE.

numbers of underground grubs, larvæ, &c. They live entirely on the insects they find in the soil; they are of a rusty-red colour, more than an inch in length; antennæ hairy, having seventeen joints; legs hairy, having twenty-one on each side. One species, *Cryptops hortensis*, is almost entirely confined to the southern counties of England; the rest are common everywhere.

Amongst lepidopterous insects—that is, those of the butterfly and moth kind—there are some species injurious to turnip crops, which are thus described by Mr Stephens in "The Book of the Farm," vol. ii. p. 79:—

"*Cerostoma xylostella* (the turnip diamond-back moth), fig. 77.—When at rest, the wings are

Fig. 77.

TURNIP DIAMOND-BACK MOTH.

closed and deflexed, and the horns are projected forward in a straight line. It is more or less brown. The upper wings are long and narrow, and, when closed, form two or three diamonds upon the back. The inferior wings are lance-shaped, and of an ash colour, with a very long fringe. Its length is  $2\frac{1}{2}$  lines. The caterpillar is green, about half an inch in length, slender, and tapering to both ends. They are exceedingly active, and on the slightest touch wriggle themselves off the leaf they are feeding on, and let themselves down by a silken thread, and remain suspended till the cause of alarm subsides. As many as 240 have been counted on one leaf; and such is their avidity, that not the smallest vestige of a green leaf is left by them. This larvæ is destroyed by a black ichneumon, named *Campoplex pamisus*."

*Mamestra brassicæ* (cabbage-moth), fig. 41, attacks the Swedish turnip.

*Mamestra oleracea* (white-line brown-eyed moth), fig. 78 (see section CABBAGE), is also an enemy to the turnip and lettuce, as well as the cabbage. This moth is of a dark rusty-brown

colour. "The antennæ have white scales; the abdomen is ash grey, with brown tufts; the

Fig. 78.

WHITE-LINE BROWN-EYED MOTH. Natural size.

feet are greyish brown, yellow-ringed below; the fore wings have no connected cross lines; the round middle spot is surrounded with white; the kidney spot is orange colour in the shape of a lunule; very delicate white and black dots are seen on the watered band; the fringes are deeply toothed, bordered by a faint white line; the under wings are ochre yellow, or dirty white, with darker shades towards the whitish fringes. The reddish or yellowish brown caterpillar has on the back, and on each side, a dark stripe, and a whitish one nearly over the feet; the under side and feet are light brown; it is dotted with black between the dark stripes. When young, and sometimes also when fully grown, the ground colour is green. The pupa is shining reddish brown, and remains in the earth during winter."—*Kollar*. It feeds upon the cabbage, turnip, and lettuce, and is best destroyed by sprinkling caustic lime over the plants as soon as the caterpillar appears, repeating the operation while they continue to appear.

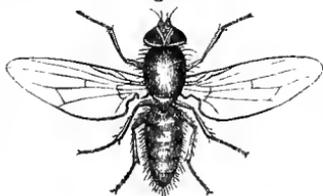

*Pontia brassicæ*, fig. 44; *Pontia rapæ*, fig. 46; and *Chrysomela betulæ*, are all more or less injurious to turnip crops, feeding on the leaves. They are, however, kept in check by the ichneumons *Microgaster glomeratus* and *Pimpla instigator*, and by the cynips *Pteromatus brassicæ* and *P. pontia*.

*Anthomyia gnava*, in its maggot state, attacks turnips during autumn, forming cavities in the bulbs. The female fly is ash-coloured, with a black line down the body, broadest at the base, and is nearly  $\frac{1}{2}$  of an inch in length, and  $\frac{1}{4}$  an inch in expanse. The male fly has a black trunk and legs; body linear, of the same colour as the female, with testaceous bands and black dorsal spots.

*Anthomyia brassicæ* (cabbage-fly), the *A. radicum* of some entomologists, fig. 79. When the maggots attack the roots of the cabbage, the roots "become enlarged and carious, the maggots revelling in the cavities. They are very similar to those of flesh-flies, being fat, yellowish white, tapering to the head, which has two black hooks. The blunt tail has two brown spiracles and some minute spines. Excepting in the depth of winter, they may be found feeding all the year. Heat, however, generates them most rapidly, for in May and June they exist at the same time as maggots, pupæ, and flies. The larvæ are transformed to bright rust-coloured horny pupæ in the roots, or they bury themselves in the earth. These cases have a few tubercles

at the head, and minute teeth at the tail. The flies which hatch from them differ so much in

Fig. 79.

CABBAGE-FLY.

the sexes, that they do not look like the same species. The male is ashy grey and very bristly; the eyes nearly meet on the crown, and the face is silvery grey, with a long black streak on the forehead; the two horns are small, black, with a downy bristle; the trunk is grey, sides whitish, with three faint broken stripes down the back; body linear, shining grey, with a black stripe along the centre; the edges of the segments are also black; two wings transparent; two balancers ochreous; legs black and spiny. Female ash grey; face silvery white; sides of the trunk pale; eyes distant, with a broad black stripe between them, of a chestnut colour in front; the body is conical at the tip; the wings are ochreous at the base; nearly  $\frac{1}{4}$  of an inch long, and  $\frac{1}{2}$  an inch in expanse.

"*Anthomyia trimaculata* is another species which attacks the roots of cabbages in summer and autumn. The male fly is light grey, reflecting white, with four black broken stripes down the trunk; three brown spots on the scutal; a black stripe on the body, which is checkered with brown; the legs are black. The female is a little larger and paler; tips of thighs and shanks reddish brown."

Regarding the diseases to which turnips are liable, the anbury and the finger-and-toes are the principal, if they are in reality distinct, which we believe they are not. The cause of these well-known diseases seems little understood; at least, opinions on the subject are at great variance one with another. Mr Marshall, in "Rural Economy of Norfolk," vol. ii. p. 33, ascribes it, according to the long-received opinion, to repeatedly cropping the same ground with the same crop, bad cultivation, and also the presence of an insect in the tap-root, by which the course of the sap is divided, and instead of the natural bulb an excrescence is produced. Mr Stephens, however, in "The Book of the Farm," vol. ii. p. 80, denies this, and we think with much better judgment. After stating the well-known fact that this disease has occurred on ground never before cropped with turnip, this high authority remarks: "If the disease were occasioned by the puncture of insects, better cultivation would not abate its virulence, but rather increase it, as the turnip would thereby be rendered much more palatable to

them. The truth is, all such diseases arise from poverty of the soil—either from want of manure, when the soil is naturally poor, or rendered effete by over-cropping. Labour, clean, and manure the soil fully, according to the condition it presents, and no anbury will appear, unless it may happen in peculiar seasons, which always counteracts the effect of culture, and affects plants in a manner similar to the want of nourishment. Insects are invariably found in the bulbs of turnips diseased with anbury, but they are the effect, and not the cause of the disease, as the habits of the insects clearly indicate." Repeatedly cropping the same ground would have analogous effect to poverty in the soil, as crop after crop would exhaust the soil of those principles necessary for the most perfect growth of the plant, and hence debility in the vegetable system would be the consequence, and a predisposition induced to the formation of these excrescences. On dissecting these swellings while in a growing state, no traces of insects are detected; but when decomposition takes place, several species of insects are then to be found feeding on the putrid mass, attracted no doubt to it by some peculiar instinct. These insects, however, will be found in the soil, and amongst the manure applied to the crop, and would doubtless remain there, and feed on other food, were the turnips free of this disease altogether.

Others, however, trace the cause of this disease to insect attacks, and attribute it to *Curculio pleurostigma*, and describe its operations thus:—"The maggot found in those excrescences so frequently met with in the Brassica tribe, particularly in old gardens, where these crops have been long cultivated, and known by the names Ambury, Anbury, Fingers-and-toes, Club-root, &c., is the larva of this weevil. It is described by Marsham as of a dusky black colour, having the breast spotted with white, the length of the body being one line and two-thirds. Clubbing often makes its appearance on the roots even while in the seed-bed, and at first assumes the form of a small gall or wart; as the plant progresses, these become more numerous and increased in size; and within each, when cut open, is found the maggot, the larva of this insect. If left undisturbed, the maggot continues to feed upon the young woody part of the root, until it arrives at its pupa state, when it emancipates itself by eating a hole through the outer bark. While the maggot continues to feed on the albumum, the excrescences enlarge; and as the albumum becomes destroyed, the sap is prevented from ascending, and the plant languishes from want of support; and this becomes evident in dry weather, or in hot sultry days, when they will be seen flagging and ultimately dying. This disease is said to be more prevalent in old garden-ground than in newly cultivated soils, and more especially where successive crops of Brassica have been grown year after year, and is accounted for from the circumstance of the eggs of successive generations being deposited in the soil, until at last it becomes completely replete with them. This disease is of more frequent occurrence in very dry seasons than otherwise, because such seasons are more favourable for

the hatching of the eggs of insects deposited in the soil. The remedies proposed are—deep-trenching, change of crops, abundant supplies of water at the roots, charcoal-dust to the extent of half an inch laid over the surface, and slightly pointed in; sulphur and also soot are applied with advantage, both of which are obnoxious to most insects; spirits of tar, dry gas-lime, the ammoniacal liquor from the gas-works, are also beneficial. Gas-lime has been applied in quantities varying from 8 to 12 bushels per acre, and, for turnips, is raked in just before sowing; while for other Brassicæ it is pointed in with a spade to the depth of from 6 to 8 inches, and applied in a larger quantity. In the case of transplantable Brassicæ, frequent removal has been attended with beneficial effects, but this is owing, probably, more to the care taken in removing the excrescences at each transplanting, than to any other cause in connection with the operation.

*General remarks.*—Saving turnip-seed, as well, indeed, as that of all brassicaceous plants, is a very peculiar branch of rural economy, requiring great circumspection in first selecting the specimens, which should always be the most perfect of their kind, and afterwards in preventing those intercourses to which all this natural order is so prone. Were cabbage, cauliflower, and turnip to be grown together, and did their period of flowering happen to occur at the same time, it is uncertain what might be the progeny from their seed. Certainly a great deterioration might be anticipated.—*Vide Sect. PROPAGATION BY SEED.* In saving, therefore, seed of any particular variety of turnip, no two sorts should be attempted in the same garden at the same time, nor should any other allied plant be suffered to flower at the same period. The finest formed bulbs should be selected in autumn, and transplanted into an open airy part of the garden, and placed, according to their respective size of growth, at from 2 to 3 feet apart each way, that the light and air may have free access to every part of the plant, while in flower, and while perfecting its seed. In spring, as the flower-stems extend in height, if only a few plants be experimented upon, they should be tied to stakes for support; if many be grown together, they are less liable to sustain injury from wind. A judicious pruning away the smallest side-shoots, particularly such as flower latest, will be of advantage to those left; and besides this, little further care is necessary, beyond securing the crop from birds, which in all gardens can be readily excluded from the seed, by covering the plants with netting, elevated a foot or two above the topmost branches. If plenty of room is allowed, the seed will ripen pretty regularly; but the first-ripened pods should not be sacrificed by being allowed to shed their seed in waiting till the smaller and later ripen also. It is better to lose the last than the first. When the seed begins to change to a brownish colour in the pods, the whole crop should be cut over by the ground, and laid upon a dry place to mature fully. The accumulated sap remaining in the stems and branches will afford them sufficient nourishment, although separated from the root,

to mature the seed. The precaution of covering with the net, while the crop is drying, must not be neglected; and when the whole is sufficiently dry, carry it to an open, airy, dry shed, and thrash it out, spreading over the floor a thick canvass cloth to receive the seed. The thrashing should not be done violently—a stout lath will be sufficient for the operation; and when the first beating is over, gather up the seed from the cloth, pass it through a sieve, and lay what passes through upon another smaller cloth, still further to dry it. In a day or two afterwards, the same operation should be repeated, when most if not all the seed good for anything will be got out. Sift and dry the seed thus secured; and when thoroughly dry, bag it up for storing away. Great care must, however, be taken that the seed is thoroughly dry, and that, until it is so, it be spread out thinly; for, if laid in too great a thickness, or even bagged too soon, it is, of almost all other seeds, the most likely to get into a state of fermentation, which would destroy its vitality. Turnip-seed, like all the other varieties of Brassica, will keep for years; and if *well* kept, will improve for the first four or five years; and, in some cases, such as early Dutch turnip, cauliflower, broccoli, &c., we have had long enough experience to be satisfied that seeds of either, if, as we said before, *well* kept, are better at the end of the seventh or eighth year than they are the season following their saving.—*Vide Sect. PROPAGATION BY SEED.* The European names are—Navet in French; Steckrube, or Rube, in German; Nabo in Spanish; Navone in Italian; Raap in Dutch.

### § 3.—THE POTATO.

*Natural history.*—The potato (*Solanum tuberosum* L.) belongs to the natural order Solanæ, and to the class Pentandria and order Monogynia in the Linnæan arrangement. The generic name is derived from *Solor*, to comfort, from some of the species soothing by stupefying. Some say from *Sol*, the sun; and others from *Sulanum* (from *Sus*), from its being serviceable in disorders of swine. The derivation may be possible, but the application is not very evident. The English name is probably derived from *Batata*, the Indian name of the sweet potato, which was known in this country thirty-three years before the introduction of the potato; or it may be from *Papas*, the name given it by the natives of Quito, where it grows wild. The order Solanæa comprises upwards of 900 species, which are found distributed over a large portion of the globe, the genus *Solanum* alone furnishing about 170 of that number. All the tribe are suspected of possessing narcotic properties; but it is thought by many that this has been exaggerated, on account of the intense and deleterious properties of deadly nightshade (*Atropa belladonna*), the mandrake (*Mandragora vernalis*), and some others that belong to it. Some of them, like the potato, contain, however, very opposite properties in the same plant. An extract from the leaves and stems is a powerful narcotic, ranking between belladonna and conium, the

poisonous hemlock; and the berries, although in a less degree, partake of the same nature also; while the tubers, when cooked, afford a wholesome and nutritive food. The water in which potatoes have been boiled is of a very suspicious character, and has been employed in the destruction of aphides on other plants—all these properties being, no doubt, known to the late Dr Neill, when he asks, "Who could, *à priori*, have expected to have found the most useful plant among the natural family of the *Lurida*, several of which are deleterious, and all of which are forbidding in their aspect?" The people in Burgundy, long after its introduction into Europe, were interdicted from either cultivating or using the potato, as it was "deemed a poisonous and a mischievous root." Liebig concludes that the deleterious or poisonous alkaloid found in the leaves and stem of the plant is formed in and around the shoot, where it germinates in darkness; but there is no evidence that the tubers are thereby rendered injurious or deleterious—or, if so, they are brought to a wholesome state by the process of boiling and roasting.

The native habitat of the potato has not been very correctly ascertained. According to Mr Darwin, it grows wild in the islands of the Chonos Archipelago, in great abundance in the sandy shelly soil near the sea-beach. Mr Low asserts it grew as far south as latitude 50°. Humboldt sought for it in vain in the mountains of Peru and New Granada. Ruiz and Pavon discovered it in a wild state at Chancay, on the Peruvian coast—a circumstance far more recently confirmed by Mr Caldcrough, who sent native tubers to the Horticultural Society of London. Mr Cruikshanks, in letter to Sir W. J. Hooker, says, "This wild potato is very common at Valparaiso; it grows chiefly on the hills near the sea. It is often found in mountainous districts far from habitations, and never in the immediate vicinity of fields and gardens." Mr Meyer affirms that he found it not only in the mountains of Chili, but also in the Cordillera of Peru. This plant appears from other authorities to extend over a large extent of latitude, and hence it is by no means improbable that each of these travellers did find it in an indigenous state at the places mentioned. Indeed, from a remark of Mr Darwin's, this appears sufficiently probable, as he found the same plant on the sterile mountains of Central Chili, where not a drop of rain falls for more than six months, and within the damp forests of the islands in the Chonos Archipelago.

The date of the introduction of the potato into Britain is involved in nearly as much uncertainty as the exact spot of its nativity. It is generally believed that the first tubers were brought to England from Virginia by the colonists who were sent out by Sir Walter Raleigh in 1584, and returned in 1586. Phillips, in "History of Cultivated Vegetables," vol. ii. p. 80, however, thinks it uncertain whether Sir Walter or his people brought it, or whether it was not afterwards sent him by Sir Thomas Grenville, or by Mr Lane, who was the first governor of Virginia. Herrist, who went out

with them, wrote an account which will be found in De Bry's "Collection of Voyages," vol. i., under the title "*Roots*." He describes a plant called openawk thus: "The roots are round, some large as a walnut, others much larger; they grow in damp soils, many hanging together as if fixed on ropes; they are good food either boiled or roasted." Gerard describes two sorts of potatoes, the one evidently the sweet potato (*Ipomœa batatas*), which was supposed to possess an invigorating property. The other sort was evidently our common sort, which he calls *Batata Virginiana, sive Virginianorum*. To the continent of Europe the potato had been introduced before its arrival in this country, and it is believed to have first found its way into Spain in the early part of the sixteenth century, from the mountainous parts of South America, where around Quito it is called papas. From Spain it reached Italy, and shortly after must have been brought into Belgium, for Clusius informs us that he received it at Viena in 1598 from Mons, a city in Hainault, to which it had been carried from Italy by one of the attendants of the Pope's legate. It appears to have spread rapidly throughout Germany in Clusius's time. It reached Ireland in 1610, and not 1566, as asserted by some writers, who most probably mistook the common potato for the sweet sort procured either from Spain or Italy, as we have no account of its reaching Europe so early, with the exception of the surmise that Sir John Hawkins introduced it in 1563, a surmise not supported by historic evidence. It was certainly used as an article of food by the Irish long before its utility was generally known in England. In 1684 it was cultivated sparingly in Lancashire, from stock said to have been accidentally thrown ashore by a vessel wrecked on the coast; while others say it was carried over from Ireland, from the estates of Sir Walter Raleigh near Cork. Be this as it may, Lancashire has from about that period been famed for the abundance and quality of its potatoes, to which the mildness and humidity of the climate greatly tends. Gerard grew them in his garden in 1597, and recommends their "being eaten as a delicate dish, and not as common food." Parkinson appears to have paid more attention to their cooking, and recommends their being "roasted, and steeped in sack and sugar, or baked with marrow and spices, and even preserved and candied by the comfit-makers." Lord Bacon, who wrote his "Natural History" shortly after the publication of Gerard's "Herbal," calls them potadroots, and gives a curious account of a method of growing them in pots. In the early part of the seventeenth century this root was grown in the gardens of the nobility as a curious exotic. Phillips, in "History of Cultivated Vegetables," vol. ii. p. 85, says, "The potato appears to have been a great delicacy in the time of James the First; for in the year 1619 it is noticed among the different articles provided for the queen's household. The quantity supplied was extremely small, and the price high, being at that time one shilling per pound."

The first instance we have met with of the potato being brought forward as an object of national importance is the letter of Mr Buckland read before the Royal Society in 1662-3, recommending the planting of potatoes in all parts of the kingdom to prevent famine. His contemporary, the celebrated John Evelyn, held them in small estimation. He says in "Sylva," writing in 1699, "Plant potatoes in your worst ground. Take them up in November for winter spending; there will enough remain for a stock, though ever so exactly gathered." London and Wise did not consider the potato worthy of notice in their "Complete Gardener," published in 1719. Bradley, a voluminous writer of the same date, says, after having described parsnips, carrots, onions, &c., "Potatoes and Jerusalem artichokes are roots of less note than any I have yet mentioned." It was not until towards the middle of the last century that they were even generally known throughout England, and their cultivation even in gardens was scarcely understood in Scotland till about the year 1740, and it was not practised in fields till about 1760. So little was their cultivation understood in 1725-6, that, as we are informed by "The General Report of Scotland," vol. ii. p. 111, the few potato plants then existing in gardens about Edinburgh were left in the same spot of ground from year to year, a few roots being taken up for use in autumn, and the remainder left in the ground covered with straw to protect them from the frost. In 1728, Thomas Prentice, a day-labourer at Kilsyth, showed the first example of planting them in the open fields; yet in no country in the world are they cultivated to so great a degree of perfection as they are in Scotland at this day.

*Uses.*—Most of these are so well known that it would be superfluous to recapitulate them all. Still there are many purposes to which they are applied not generally known; to these, therefore, we shall now only refer, premising, however, that those curious in the matter will find an interesting paper on the subject in the 1st vol. of the "Gardeners' Magazine," p. 438, in which thirty-one different uses of the potato will be found noticed. An agreeable brandy has been produced from the roots by distillation—an invention due, according to the "Memoirs of the Royal Academy of Sciences in Sweden for 1747," to Mr Chas. Skytes. He states that an acre of potatoes, compared to an acre of barley, will yield a spirit in the proportion of 566 to 156, even admitting the potato to be planted on worse ground than the barley. Dr Anderson states in the "Bath Society," vol. iv. p. 50, that he had distilled from 72 lb. of potatoes that had been properly fermented (with no addition except yeast), an English gallon of pure spirit, considerably above proof, and about a quart more below proof. The tender tops are used, both in Canada and Kamtchatka, as spinach; the boiling, no doubt, freeing them of their narcotic property. The starch or fecula obtained from the roots is now extensively used to adulterate and even pass off as a substitute for sago, starch, arrow-root, tapioca, &c.—a very harmless imposition, and a great boon to cultiva-

tors, particularly since the appearance of the potato epidemic, as those judged unfit for the food of man in their natural state, are manufactured into representations of these supposed nourishing articles. Mrs Morris, a London lady, so early as 1807 discovered that the liquor obtained in making potato-starch would clean silk, cotton, or woollen goods, without damage to the texture or colour. Potato fecula is by many preferred for making soufflés, and is for that purpose, as well as others connected with domestic economy from a soufflé to macaroni, sold in the shops under the learned names of *Fecule de Pomme de Terre*, and others of more recent date, with which the public allows itself to be gulled. A size is made from potatoes, which has great advantages over common size, for the purpose of white-washing, as it does not smell, and it has also a more durable whiteness. Yeast may also be made from the roots, fit for the use either of the baker or the brewer.

Potatoes are extensively employed by bakers to mix with their flour in making bread, and bread so made is considered lighter, and by many preferred to that made of flour alone. They are washed and peeled, and the pulp grated down, and in that state are mixed with the dough. Before potatoes became scarce in consequence of the disease, and their value approximated so near to that of wheaten flour as to render the operation scarcely remunerative, almost all cottagers, and indeed many families who baked their own bread, used them constantly. We know well that families of distinction, who keep their own baker, have potatoes mixed with most of their fancy bread, rolls, &c.; and this is done on their parts not for economy, but for improving the lightness of the bread, and rendering it more digestive.

Much has been said on the value of the potato as an article of food, and there can be little doubt that more dependence has been placed on it, as such, than it deserves. It is more than thirty years ago since Mr Cobbett stigmatised it as "the accursed root;" and that extraordinary man foretold then the disappointment that would in course of time arise from its too extensive cultivation. Without entering into the question of political economy, we may safely assert that much of the human misery that has taken place both in Ireland and the Highlands of Scotland may be traced to a too implicit reliance on this root as an article of human sustenance. Wherever the potato can be advantageously cultivated, there the cereal crops will prosper also; and if we analyse the produce of an acre of wheat, barley, or oats, with one of potatoes, the difference in the amount of nutritious matter will be sufficiently evident.

Man is said to be made up of a bundle of habits. Before the introduction of the potato, the Jerusalem artichoke was much appreciated, and were that plant sufficiently hardy to stand our climate, or rather to perfect its tubers within the same space of time as the potato, the loss of the latter would not be regretted, as the former is far more wholesome and much more nutritious. It maintained its place in public estimation even long after the potato was intro-

duced. The potato having no peculiar taste, like bread it can be used long by the same individual without becoming unpalatable, and is no doubt a useful vegetable to be eaten along with butcher-meat upon the same principle that most other vegetables are. Long use has also habituated us to it, so that for such purposes its loss would be felt for a time; but as an article of direct food, on which thousands are to depend for sustenance, its total extinction would be no great loss. And this the less so, seeing we have substitutes for it as easily cultivated and as productive, could we only rid ourselves of a confirmed habit.

*Propagation.*—The usual and most expeditious way is to propagate by planting medium-sized tubers whole, or the larger ones cut into sections or sets, as they are technically termed, having one eye or bud to each. By this means a crop is obtained the same season, and the variety, if not subjected to a considerable change of climate, continued for years without much change in character or deterioration in quality. It is also propagated by seeds, when new or improved varieties are wished for, and by this means most of the sorts at present in cultivation have been obtained. The process has also been had recourse to since the appearance of the disease, thinking thereby, by getting a new breed either from seed home-grown, or imported from its native country, that a new progeny with increased vigour would be produced. These hopes have not been realised; seedling plants, from home-grown or imported seed, have suffered almost alike. Seed has, however, produced improved varieties; but unfortunately the process has been so carelessly gone about, that, with very few exceptions, we do not find any satisfactory information as to the means employed. It is probable much of the success has been the result of chance, or the natural proneness of the plant to run into variety from seed, some of which may be good, others inferior to the parent plant. It is also propagated by layers and cuttings, modes that can only be considered expedient when sets are scarce, or when it is desirable to multiply a new or scarce variety.

*Propagating the potato by cuttings* has for several years been extensively employed by Messrs Hay and Sangster of London, with a view to restore vigour in the plant and arrest the progress of disease, by obtaining through this means a healthy progeny. In procuring cuttings, the potatoes

are placed in spring on a moderate hot-bed, as they think it important that the cuttings should be as short a time as possible on the old tubers. When the young shoots have attained the height of 4 or 5 inches, they are cut off much in the way dahlia cuttings are taken from the roots—that is, taking no part of the old tuber along with them. They recommend that the planting of the cuttings in the open ground should be proceeded with before the 20th of May (that is, for the latitude of London), and, at planting, that 1 or 2 inches of their tops should be left above ground, and a slight watering given if the ground is dry. In this way they have secured a healthy crop over 5 acres of ground from the tubers produced by the plants originated by cuttings in the preceding year. “The only fault,” they say, “in planting cuttings, is that the tubers grow too large, and some anything but handsome;” but this must be put up with, if growing any description of potatoes three years by that process is to bring the stock to a healthy state, which they have no doubt will be the result.” By an analysis of the tubers grown in the ordinary manner by sets, the amount of fecula or starch was found to be only 11 $\frac{3}{4}$  per cent, while those originated by cuttings gave 15 $\frac{1}{2}$ ; and upon a subsequent analysis the latter were found to yield 17 per cent, which is nearly the maximum amount to be expected from healthy tubers. How far Messrs Hay and Sangster are correct in thinking that a deficiency of saccharine matter in the potato, as it now exists with us, is the cause of the disease, may admit of doubt, as also that their process has the effect of restoring to the tubers that element; one thing, however, is certain, that potatoes struck by cuttings by ourselves have yielded an abundant, early, and healthy produce.

Layers of the young shoots will also root freely; but the advantage of the latter mode is, we think, very questionable, except for the purpose of multiplying any rare or new sort expeditiously.

*Propagation by seed* is a very simple affair. All that is required, where the more nice and scientific process of inter-marriage, or cross impregnation of the pistil of one sort with the pollen of another, has not been duly attended to, is to select the largest and best ripened apples

(or plums, as they are called in some places) in September or October, and to wash out the seeds and keep them dry till spring, when they should be sown in drills in a warm situation; or the seed may be retained in the apples, and those buried in dry dust till spring, when the seed can be easily rubbed out. When the young plants have reached the height of 2 or 3 inches, they should be thinned out to 5 or 6 inches apart, and the thinnings may be transplanted at the same time. Towards the close of the season the tubers will have ripened, and, as they are small, select the largest, as they are the most promising, and keep them for planting in the February or March following, if circumstances prevent them being planted as soon as they are dug up and examined. The autumn following will determine their size and productiveness, and any old woman, after the first boiling, will give ample evidence as to their quality.

"A variety of the potato" originated from seed "is generally considered to continue about fourteen years in perfection, after which period it gradually loses its good qualities, becoming of inferior flavour and unproductive."—*Cottage Gardeners' Dictionary*, p. 739. To this rule there is, we think, at least one exception, and that is in the case of the old and highly-approved American early, which we have now known for about half a century, and see little difference in it in either of these respects. The case is very different with others, for those of our early days are now unknown even by name, and it is possible that the variety above named forms the exception to the above rule. May this not have been the original variety imported direct from America? The types of other varieties may have reached us from a more southern latitude, and been of larger size, more delicate, and of different qualities. The early varieties do not readily produce seed. This may be, however, effected, when desired, by planting the sets on little mounds of earth, and training the stem to a stake for support, and washing the soil from the roots, so that only the points of the fibres enter the ground. The plants will blossom and perfect seed.

Some sorts of potatoes produce seed, while others do not. Most of the late varieties produce seed freely; the early

sorts rarely do so. This peculiarity was not unnoted by Mr Knight, who also discovered the cause, and accounts for it in this manner: "I suspected the cause to be the preternaturally early formation of the tuberous root, which draws off for its support that portion of the sap which, in other plants of the same species, affords nutriment to the blossoms and seeds; and experiments soon satisfied me that my conjectures were well founded." His experiments in connection with this matter will be found fully recorded in the "Philosophical Transactions for 1806," and also in the "Transactions of the Horticultural Society," vol. i. p. 188. Unless the object be to secure seed, experience has proved the advantage of cutting off the flowers before the fruit is set. Knight accounted for this, and states that the process will increase the gross weight per acre by about 1 ton in weight; subsequent experience has confirmed this opinion.

*Planting.*—The usual season for planting garden potatoes is from February to the end of April, the early varieties being planted first. Of late years autumnal planting has been resorted to as one of the many means recommended for saving the potato from the attacks of the mysterious epidemic, and, no doubt, with very beneficial effects, admitted by many as well as experienced by ourselves. Many, however, view this as a chimera. Autumn planting is by no means a new feature in cultivation; we have practised it for upwards of thirty years, founding our data upon the simple and indisputable fact that the soil is the natural matrix for the tuber to be preserved in during its season of repose. As regards precise seasons for planting, much depends on soil and situation. In all dry and warm soils, planting may commence in November; or, indeed, the tubers may be replanted the same day the crop is lifted: but this will not much hasten the season of their coming to maturity, only plants originated from this early planting will be stronger in spring on account of the tubers losing nothing of their elaborated sap, which all those taken up and kept, if not completely excluded from the air and kept in a low temperature, must inevitably do. With this extra strength, therefore, they push away stronger in spring, and not only arrive at a useful state

sooner, but are better able to resist spring frosts than those which are so much weaker. Planting, therefore, may be gone on with from November to April, when the ground is dry and free from frost.

"Planting in the open ground is best done in October and November, and may thence be continued until the end of March. This last month is the latest in which any considerable plantation should be made. They will succeed if planted in May or even in June, yet it ought always to be kept in mind that the earliest planted, especially in dry soils, produce the finest, healthiest, and most abundant crops."—*Cottage Gardeners' Dictionary*, p. 738.

Dr Lindley, in an excellent article on the culture of the potato, "*Gardeners' Chronicle*," 1842, p. 155, remarks, "The period of planting should be as soon after the 1st of March as circumstances will permit." "I have uniformly found," Mr Knight says, "that, to obtain crops of potatoes of great weight and excellence, the period of planting should never be later than the beginning of March." This is in order to give the potato as long a summer as possible. From experiments made some years ago in the garden of the Horticultural Society, it appeared that a crop planted in the first week in March exceeded that planted in the first week of April by about  $1\frac{1}{4}$  tons per acre. It must be obvious, however, that the propriety of planting thus early will depend upon the nature of the soil, and that it is too early for wet heavy land, although it is the best season for light soils. In reality, land cannot be advantageously planted with potatoes until all the superfluous moisture has drained away or evaporated.

In some parts of England, sets for the earliest out-of-door crop are planted in October, choosing a dry sheltered situation and light soil. The sets are placed 8 or 9 inches deep, and the surface covered over with straw, fern, or dry litter, so as to exclude frost, retain the heat absorbed by the soil during summer, and effectually throw off rain; in fact, to retain the heat in the soil, and prevent its escape by radiation. The ground is generally set off into beds with deepish alleys between them, which receive the water thrown off by the covering. The plants

appear above ground in March, and are protected from frost by hooping them over and covering with tarpauling. Early potatoes are in this way procured in May, or by the beginning of June, even in Lancashire.

*Preparation of the ground for planting.*—Amongst the many instances of mismanagement to which this plant has in many cases been subjected, is a disregard to the thorough working of the soil in which it is planted; for although the tubers are produced at no great depth under the surface, still the food-collecting roots penetrate to a considerably greater extent. Trenching the ground, or, in absence of this, deep-digging, is an imperative condition to their most successful cultivation, and, in carrying out either of these operations, the manure, if such is to be applied, should be completely incorporated through the soil. The practice is absurd, although sanctioned by most writers on the subject, as well as followed by cultivators for ages, of placing it in immediate contact with the set or tuber in the trench or drill prepared for their reception. No doubt the slight fermentation which must of course take place when very rank stable-yard manure is employed, gives a certain degree of excitement to the tuber, and may, to some extent, cause an earlier development of roots; but no sooner are they produced than they begin to extend in length, and travel with a rapidity in proportion to their growth as far as they possibly can from the mass of manure placed by the planter for their special use. If the doctrine is to be considered valid which has been propounded by vegetable physiologists, that plants derive their chief root-support from the food collected from the soil by the spongiolets which are placed *only* at the extremities of the minute fibres, it appears pretty clear to us that the plant derives little if any advantage from the manure so placed, beyond the slight stimulus given during the short time fermentation is in operation, immediately after the tuber is placed either over it or under it (for they are placed in both ways); and that manure incapable of fermentation is not only absolutely useless but positively injurious, tending, as has been asserted by many of our most intelligent cultivators, to encourage

greatly the disease under which the potato is now suffering.

Manure, to be beneficial to any plant, must be placed so that it is within the reach of the spongiolets; and as they ramify in all directions *away from* the seed, tuber, or whatever else may constitute the origin of the plant, it appears pretty clear that it should be as thoroughly mixed with the soil as possible, and hence confining it within the narrow limits of a drill is of all modes of application the most wasteful. In accordance with these views, they are right who recommend planting the potato in ground enriched by previous manuring, whether employed for the last crop, or applied to the ground without any crop at all, because they get rid of one of the evils stated above—namely, encouragement to the disease. Manure, to be useful to any crop, must become soluble, and this condition does not come immediately about in the case of such manures as rank stable-litter: its application, therefore, must be regarded as of little service to the present crop; but that it will be so to the succeeding crop is to be expected.

The mode, therefore, of preparing ground for potatoes, as usually practised—viz., planting them in drills or trenches along with manure—must be regarded as erroneous; and, as we have already observed, if manure is to be applied, let it be so during the process of trenching or digging, and let it be as completely mixed with the soil as possible.

The methods of planting the potato are numerous. That of planting with the dibber, next to that of placing them in trenches amongst rank manure, is the worst. The rapidity with which the former is accomplished is an inducement with many, but it is a very imperfect one, unless the ground is very dry, and the dibber of a diameter to make a hole sufficiently wide to admit of the set or tuber falling to the bottom; and this is not easily done when the soil is light or gravelly, as portions of it will fall in before the set is introduced, and consequently some will be much deeper planted than others. The better way is, to open a drill with a hoe or spade, of an equal depth throughout, and to set the tubers in it, and afterwards draw the soil over them, so that in most cases there may

be 6 inches of mould over them when finished. This insures their being all placed at a uniform depth, and leaves the mould quite open and soft both under and above them,—affording, in the first place, a proper state for the young and tender roots pushing their way into it; and, in the second, allowing the rains to sink in, and the solar heat and air to penetrate, and admitting of an uninterrupted process of evaporation taking place.

In regard to distance, much depends on the sort. The small-growing early kinds may be set in rows 15 inches apart, and from 8 to 10 inches in the line; but for the later and stronger-growing sorts, 20 inches to 2 feet should be allowed row from row, and from 12 to 15 inches in the line. There is no gain in too thick planting.

In ordinary garden-soils the sets may, with every propriety, be placed 6 inches under the general level of the surface. In damp wet land the sets should be placed on the surface of the dug ground, and the mould drawn over them, in form of a broad flat ridge, say 6 inches in height at the centre, and 10 inches at the base. Where the ground is very wet—but such is very unfit for the potato—the old lazy-bed manner may be followed, which is by dividing the ground into beds of 4 feet in breadth, leaving 2½-feet alleys between. Dig the bed deeply over, set the tubers in rows across, at the distances stated above, and cover them at first by laying 4 inches of soil, taken from the alleys, over them; and in course of a few weeks afterwards, but before the shoots appear above ground, lay over that 3 inches more from the same. In such cases, ridges may be thrown up, from 1 to 2 feet in height, and from 2 to 3 feet apart; and on the top of these set the tubers, and cover them over as above. These are extreme cases; and when the soil is incapable of being thoroughly dried by draining, to admit of the process being carried on in a more business-like manner, it were better to crop the ground with some other crop.

In regard to the depth the sets should be put in the ground, much depends on its texture—as to whether it is light and pervious to solar heat and air, or whether it is retentive, and impenetrable to either. From experiments made in the London Horticultural Society's garden, the following results have been arrived at:—

“In warm dry land we regard 9 inches as not too deep, provided the sets are large and strong; in cold stiff soil 4 inches would be better: 6 inches is a good depth in average soils, and indeed may be considered the best depth in most soils. Weak sets do not come up well at 9 inches deep; but, on the contrary, 4 inches is too shallow, occasioning the tubers to be partially exposed to the light, and hence to become green. If, however, the land is so shallow as to admit of no greater depth, then more space must be allowed between the rows for earthing up. In one of the experiments above alluded to, different depths were also inquired into, when the rates of produce were nearly as follows: 3 inches deep gave 13 tons; 4 inches, 14 tons; 6 inches,  $14\frac{1}{2}$  tons; and 9 inches, 13 tons. At so great a depth as 9 inches, sets are apt to perish, unless the soil is dry, light, and warm. The deeper, however, the sets can be safely inserted the better, for the following reason: Potatoes are formed on underground branches; the deeper set, the more branches will be formed before the shoots emerge from the soil, and consequently the more ample will be the means possessed by the potato plant for forming tubers. The important practice of earthing up is designed to effect the same end by compelling the potato stem to grow as much as possible underground.” Subsequent experience has proved that earthing up is of little consequence, if the potato has been planted from 6 to 8 inches deep in the first instance.

*Size and choice of sets.*—Since the prevailing malady has been so destructive to the potato, sets—that is, cut sections of the tuber, having one eye or bud each—are much seldomer used than formerly. The larger the set is, the stronger we would naturally expect the plant to be, on account of the greater amount of elaborated matter it contains compared with a smaller one; but this does not appear to be the case; no one set need have more than one eye or bud. Some have placed much importance on the end of the potato from which the set is cut, and recommend the rejection of the watery or less ripened end of the tuber, as well as the root end, or more ripened portion also, assigning as a reason that the former has too many small eyes, and that plants produced from it are apt to run too much to haulm; and to the

root end they object, fancying that it is tardy in growth, and more liable to disease. They say, Make choice of the middle of the potato, which, if cut in two, will afford two sets, having one eye each. This appears to us to be merely the shadow of the well-known fact that fully-matured potatoes, fit for food, are less proper for seed than those that are much less perfectly ripened, and hence the demand for seed-potatoes from upland and late localities, where, in fact, the potato seldom ripens to full perfection. Physiologically, there is a difference between the two ends of a potato; practically viewed, it is so small that it may be little regarded. The late Mr Main was quite of this opinion, and set the whole down as a mere matter of speculation. In the present condition of the potato, whole tubers are preferred to cut sets, and these are usually selected from the medium-sized ones. The only objection that can be started against the employment of whole tubers is the number of eyes they have, compared with a mere section, which may be cut with only one. This objection is, however, easily remedied by the careful destruction, by the touch of a red-hot wire, of all the eyes but one; but this should be done with as little injury to the skin of the potato as possible, else the escape of its juices may be as great as in a section cut from a larger specimen. Mr George Lindley was of opinion that sets with only one eye in each, produced the crop ten days or a fortnight earlier than those having two or more eyes left on.

We have not planted sets for years, but use the medium-sized tubers whole. The late Mr Knight was of opinion that very small potatoes produced a much later crop than when large ones were used for seed: this is to a certain extent true, because they are too imperfectly matured, and therefore we never plant them. He also placed considerable importance on the position the sets are placed in at planting. In “*Trans. Hort. Soc.*,” vol. iv. p. 448, he says, “When the planter is anxious to obtain a crop within the least possible time, he will find the position in which the tubers are placed to vegetate by no means a point of indifference; for these being shoots or branches which have grown thick instead of elongating, retain the disposition of branches to propel their sap to their leading buds, or points most

distant from the stems of the plants of which they once formed parts. If the tubers be placed with their leading buds upwards, a few very strong and very early shoots will spring from them; but if their position be reversed, many weaker and later shoots will be produced, and not only the earliness but the quality of the produce, in size, will be much affected.

To the selection of sets some have attached great importance; for ourselves, we prefer, as stated above, medium-sized whole tubers, as these are not over-ripened, and because they do not require to be cut as larger ones do. Large tubers have been recommended, but have been shown to be of no advantage whatever. It has also been proved that, if the tubers are over-ripened, they are apt to produce disease. It is, therefore, better to take up the seed-potatoes before they become over-ripe; or, still better, to purchase seed from upland situations, where the potato seldom ripens to full maturity.

The argument of those who advocate the planting diseased tubers in preference to sound ones, is practically, that they soon rot away after the young shoot has begun to germinate, while sound sets are apt to remain till the ripening of the crop, retaining in themselves the germ of the disease—thus showing an effort, on the part of nature, to throw off the disease. Professor Lindley on this point remarks, "Gard. Chron.," 1850: "It is possible that the morbid matter which causes disease may disappear in the general decay of the tuber, in the one case, and may remain unchanged in the other, prepared to seize upon the haulm as soon as it is ready to receive its influence." The experiments of Mr Smith, of Wokingham, Berkshire, appear to be very conclusive in this respect, and highly deserving of our attention. Mr Smith planted *very much diseased sets* on the 18th of March, the crop from which was ripe and taken up on the 2d of August, perfectly free of disease; while sound ones of the same variety, as well as others, were planted in February, and, being taken up during the August following, were found *very much diseased*. *Very rotten late* potatoes were planted by the same gentleman in November, 6½ inches; over the sets were first laid 2 inches of the natural soil of his garden, then a layer of half-decayed weeds, and over that a covering

of the same earth. This crop was taken up also in the beginning of August, and was found *without disease*. These experiments were made from 1846 to 1849; and a person in the same town repeated the experiments in 1850, with exactly the same results. Whatever deductions may be drawn from these experiments theoretically, it will be admitted they are of great practical importance.

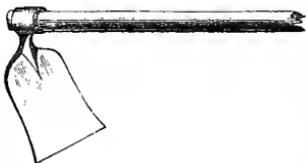

*Subsequent cultivation.*—As soon as the plants are fairly above the surface, hoeing and surface-stirring should be commenced, as few plants thrive better in an open and oft-disturbed soil. The very early crops should have the earth drawn around each plant in form of a cup, to serve as a shelter from the cold winds, which are a great enemy to them during early spring: a similar shelter will not be produced if earthed up in the usual form, which leaves them exposed on the top of the ridge. The draw-hoe, fig. 80, is well adapted for this earthing-up purpose, while implements penetrating much deeper into the soil must be used for loosening the ground between the rows.

Of the implements used in potato culture, the following may be given as examples:—

*Draw-hoes*, fig. 80, are amongst the most useful of all garden implements: they are employed

for destroying weeds, stirring up the surface-soil, drawing drills, and earthing up crops. They vary in size and form—the smallest, which is used

Fig. 80.

DRAW-HOE.

for thinning out seedling crops, being 1½ inches broad at the face or cutting part, and the same in depth of blade. There is attached to them a hose, 2 inches in length, for receiving the handle, which is straight, varying in length from 18 inches to 3 or 4 feet, according to the purposes for which they are intended. The shortest of these are very dexterously used by English labourers for thinning turnips which are sown broadcast, using one in each hand. The largest is 9 inches in the face and 3½ inches deep in the blade, and are almost all now made so that the hose part for receiving the handle is riveted on to the blade, as shown in our figure; formerly they were forged all in one piece, the hose part being on the top of the blade. The neck of the hose-piece should be slightly bent, so that when the operator is standing nearly upright, which is the easiest position for him, the face or cutting part of the blade may be at an

angle of 68°, which is the best suited for entering the ground. From the smallest to the largest there are intermediate ones, differing in size, in general, to the extent of half an inch in length of face, and denominated 2½-inch, 3-inch, 3½-inch, and so on upwards to 9-inch hoes. Hoes in form and proportion to that of our fig. 80 are the most common in use. There are,

Fig. 81.

TRIANGULAR DRAW-HOE.

however, other forms, such as fig. 81, which is triangular in shape, having each of its sides calculated for cutting up weeds and slightly loosening the surface. It is used also for drawing drills, the corner points being well adapted for the purpose. The Vernon hoe and the Spanish hoe have been already described, page 38.

Fig. 82.

DRAW-HOE AND RAKE COMBINED.

The compound hoe, or draw-hoe and rake combined, is a useless affair. We notice and figure it (fig. 82) to give us an opportunity of stating how much better it would be to have each as a

separate implement. Nearly twenty varieties of draw-hoes are figured in the "Encyclopædia of Gardening," all, with three or four exceptions, examples of those used in the rudest state of cultivation, and inferior to those of the present day. *Savage's surface-stirrer*, fig 83, is a useful implement belonging to the

Fig. 83.

SAVAOE'S SURFACE-STIRRER.

hoe class. It may be described as a common hay-fork, of rather more than double the length of prongs, which are bent over about the middle, thus forming a two-pronged scarifier of considerable power and utility. The prongs are 3 inches apart, and 4 inches long from the bend to the points, but there is no reason why they should not be double that length. The operator, as in all cases with similar tools, walks backwards, while he presses the points of the implement into the soil, and draws it after him, stirring the ground as deep as the prongs will reach between rows of potatoes and other culinary crops. Such stirring implements are far more useful than the common draw-hoes, which, from their construction, cannot enter the ground to a sufficient depth.

Fig. 84.

GUERNSEY PRONG.

Fig. 84 is an excellent implement in the section of hoes, and is known in the south of England as the *Guernsey prong*, being much used in that island. It is thus delineated and described in "The Gardeners' Chronicle" for 1851: "It is something in the shape of a hammer, the head flattened into

a chisel an inch wide, and the fork the same. The whole length of this prong is 9 inches, and it is attached to a staff 5 feet long. Such an implement is light and easy to use; it requires no stooping, and will tear up the deepest-rooted weeds." Its great utility, however, is to deeply stir and pulverise the soil.

Fig. 85.

GLENDDINNING'S PICK-FORK.

*Glendinning's pick-fork*, fig. 85, is a somewhat similar implement, and used by its inventor upon his strong and stubborn soil with great economy of time and advantage to the soil.

Fig. 86.

BLOOMFIELD HOE.

The *Bloomfield hoe*, fig. 86, is much used in Norfolk. It is somewhat like the common draw-hoe, but having the advantage of keeping itself clear of mould at the neck, which the common hoe has not in consequence of the shortness of the neck, or that part which connects the blade with the handle. The specimen we have given, fig. 80, is, however, less objectionable on this account, as will be seen by the manner the blade is attached to the handle.

*Gidney's improved Prussian hoe*, fig. 87. This is an excellent instrument, when cutting down weeds only is the object, and where the soil is not to be deeply stirred. The blade is set at such an angle that it shaves down the weeds just below the surface, and leaves them uncovered; whereas the old hoe covers up the fallen weeds, and this aids them to root afresh. It is well calculated for hoeing flower-borders, and can be usefully employed in the kitchen-garden for hoeing foot-paths between beds, or amongst young crops where seed-weeds are appearing. The face of the blade of the specimen our figure is taken from is 5 inches long, quite straight, the back rounding off towards the point, which is acute. The breadth of the blade is 1½ inches. They may, however, be made both larger and smaller, according to circumstances.

Fig. 87.

GIDNEY'S PRUSSIAN HOE.

*Dr Newington's hand-cultivator*, fig. 88, is of the hoe-stirring section. The frame or head-piece is 16 inches wide, of iron or heavy wood, to press the tines into the ground without much pressure being applied by the operator. It is fitted with three strong curved tines very sharp at the points, and which, when the implement is drawn forward, stir up the ground from 6 to 9 inches in depth. It is also fitted up with three shares for drawing drills for seed-sowing. It is the type of fig. 89, which Dr

Newington calls his "*Patent hand-row cultivator and drill-hoe.*" The head and handle are much

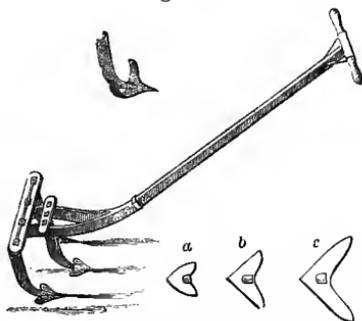

Fig. 88.

NEWINGTON'S HAND-CULTIVATOR.

the same as in the last, only the head is so constructed that when the tines (three) at present

Fig. 89.

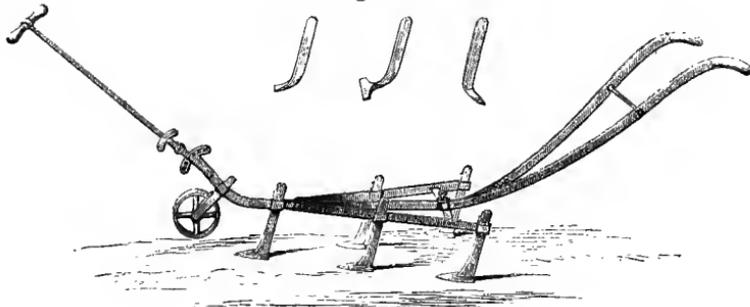

NEWINGTON'S HAND-ROW CULTIVATOR.

shown as affixed to it are removed, hoes of different sizes, *a*, *b*, and *c*, can be substituted, and in this form it acts as a weed-killing hoe; and these hoes are placed like the tines, one in the centre of the front bar or head, and two in the hind one. A moulding-board for earthing up has also been added to it, but we think with much less effect than in Sievewright's improvement upon it, which, although acting upon the

same principle, is every way a superior implement.

*Sievewright's improved cultivator* is one of these contrivances for the economising of labour, and is thus described by him in "*Gardeners' Chronicle*," 1849, p. 500. After premising that the machine has been most effectually employed in hoeing between drills, grubbing up ground to the depth of from 5 to 6 inches, and earthing up between potatoes and cabbages, &c., the intelligent improver proceeds: "When I use it for hoeing between drills, I use flat tines, which are five in number; the transverse bar at the back expands to the width of 21 inches, or contracts to 13 inches; and should even this latter width be greater than the drills will allow of, I take out the two hind tines. There is a weight which is fixed at pleasure on any part of the bar running through the centre, the position of which is regulated by the way in which you are using the machine, and which keeps it working steadily." This is a circular piece of cast-iron attached; and one, two, or more may be used, according to the weight required. "When I use the machine for grubbing up ground, or for working it into a fine state, I change the flat tines to a set which I have, similar in form to those of a common grubber: in this way I prepare the ground for the reception of a second crop, saving the expense of digging; and, when no manure is required to be buried in, doing the work far better than the spade. When earthing up potatoes or cabbages, the front tine is left in, the four hinder ones taken out, the moulding-boards put on; and as the transverse bar expands or contracts, I am enabled to earth up potatoes 21 inches between the rows, or cabbages at 13. The wheel in front regulates the depth to which the tines enter, and keeps them to a uniform depth in the soil; the hind wheel can be applied for the same purpose, and, where the ground is rough, has the additional effect of steadying the machine." In our own practice with this excellent machine, we place the weight referred to above here, finding in our light soil the hind wheel of little service. "The whole machine, which is of iron, is very light, and the work which I have described it as doing is quite within the power of a lad. The work a man could do with it would not be less than 2 acres per day, hoeing between turnips, at 2 feet apart; the grubbing he would do nearly

Fig. 90.

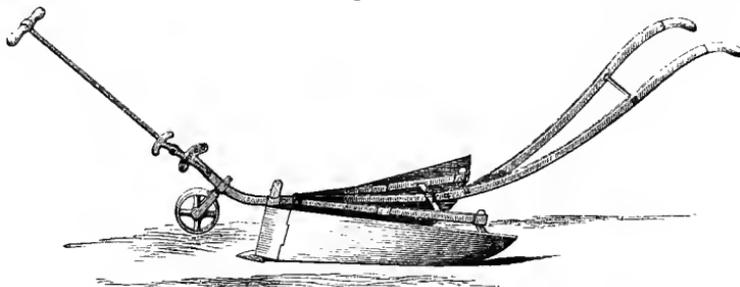

SIEVEWRIGHT'S CULTIVATOR IMPROVED.

as quickly; and would certainly earth up potatoes at the rate of an acre per day." Through the courtesy of Mr Sievewright, who early directed our attention to this machine, we have had two in operation during the last three years, and can corroborate all Mr Sievewright has said about it.

The modification of this implement, shown by figs. 90, 91, possesses, we think, important improvements on both Dr Newington's and Mr Sievewright's machines, both of whom had in view mainly its adaptability to the power of one man. Now we do not exactly see wherein there is any decided economy in this, and have there-

Fig. 91.

IMPROVED CULTIVATOR WITH EARTHING-UP BOARDS.

fore adapted ours to be wrought by a man and a boy. In both of the former the operator had to walk backwards—a position in which his physical power could not be exerted to its greatest advantage. A gain, in stony and hard ground the machine was found ineffective; nor could the ground be stirred so deep, nor the other processes so satisfactorily accomplished, as when a man's whole power is directed to drawing it forward, while a boy guides it behind; and the two lift it more conveniently at the end of each row, and introduce it into the next, without disordering or dirtying the gravel walks at the ends of the quarters. Our other appendages will speak for themselves.

The grubbing-tines are the same, as are also the angular hoes, which fit into the same holes in the frame as in Mr Sievewright's; and the moulding boards are similarly attached. We have, however, added the stilts, which enable a boy to regulate the direction of the machine behind; while the man who draws it in front is left to exert his whole strength in pulling it through the ground, which he could not do to anything like the same advantage were he to walk backwards, and with the guiding of the machine to attend to at the same time. By gaining this additional force, the tines or grubbers can be let into the ground to double the depth they formerly could, which is an important matter, and to a certain extent supersedes the operation of digging in all loose and workable soils. It is true, weeds are not so completely buried by grubbing as by turning them in by digging; but garden-ground in a highly-cultivated state should be clear of weeds; and even should they exist, the triangular hoes are to be fitted in, and the ground run over by the machine the day previous to the grubbing taking place. The expedition with which both these operations are accomplished, bears in no case anything like a relative proportion to the time occupied in digging ever so superficially the same breadth. The machine is so con-

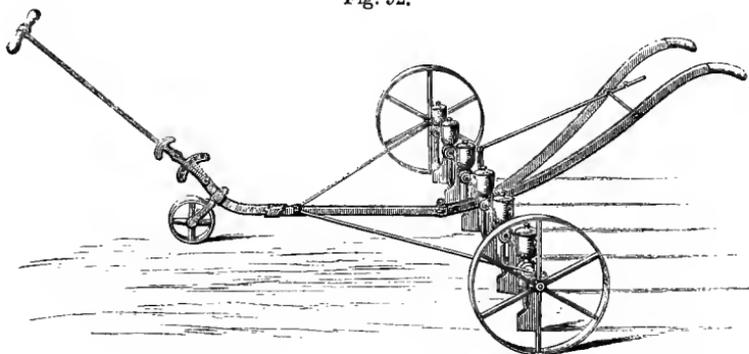

structed that the frame can be contracted or expanded to any extent to meet the difference in the breadths between all garden crops; and the same applies to the moulding boards also. With the improved machine which has been manufactured for us by Mr Slight, the eminent engineer, and which has been constructed to our entire satisfaction, we can grub to the depth of 9 inches, or hoe between the rows of crops, or earth up an acre of potatoes per day, at the cost of the wages of a man and a boy—say 3s. We may also state that we hold no exclusive right in this machine, it being a combination of former principles adapted by us to horticultural and nursery purposes with a view to the economy of time, and doing the work better than by the ordinary operations of shallow digging and hoeing, and the still more laborious operation of earthing up with the draw-hoe. These machines may be seen at the works, and procured of Mr Slight, engineer, Leith Walk, Edinburgh.

These are the parts embodied in both Dr Newington's and Mr Sievewright's implements; but to these we have added a drilling and sowing appendage, fig. 92, which not only draws the drills more equal in depth and distance than can be done by the ordinary process of using the garden-line and draw-hoe, but saves three-fourths of the time, and lessens the evil of treading the ground in an equal proportion—a most important advantage when the soil is wet. The drilling and sowing appendage is fitted on the frame, and covers a space of  $4\frac{1}{2}$  feet in breadth, so constructed that the drills can be drawn to any distance apart, varying from 6 inches to 18 inches; and from 4 to 6 drills can be opened at the same time, and the seed deposited in them. The coulters that open the drills are placed on the front of the cross arm or bar; the boxes for containing the seed are placed on top of it; and the delivering tubes, for conveying the seed from them to the drills, are placed immediately behind and within these coulters,

and reach to within 2 inches of the drill, by which the seed can be sown even in windy weather, when it could not be safely done by hand. The lower ends of the tubes are also sloped off,

by which the seeds are readily seen as they fall. A set of similar coulters is placed behind the cross arm or bar, but somewhat wider than those in front, and reversed in their position, so

Fig. 92.

DRILLING AND SOWING MACHINE.

that as the seed is dropped in the drill, and the machine in motion, these latter cover the seed by drawing the soil, pushed aside by the opening coulters, over the seed, which finishes the operation.

The quantity of seed delivered is regulated by the extent of opening in the delivering-tubes, which can be graduated to any extent to suit such seeds as onions, turnips, &c.; and can be entirely stopped at the ends of the rows, by the boy who guides the machine behind simply raising the iron rod shown between the stilts.

In commencing the operation of drilling and sowing, a line is stretched from one end of the ground to the other: along this line either the right-hand wheel, or the right-hand drill-coulter, according to circumstances, is to travel, so that the drills may be set off straight at starting. The machine is drawn along to the other end of the ground by the man, while the boy guides it along the line—thus opening, sowing, and covering in at once the number of drills the machine is set to. When the first series of drills is finished, the machine is turned, and proceeds in like manner to the other end of the ground, performing the same operation, the boy keeping in this case the left-hand wheel exactly upon the previous wheel-track. By this means, we believe, 2 acres of onions or turnips could be sown per day. Like all sowing-machines, this is best adapted for what are known as round seeds, such as rape, turnip, cabbage, onions, &c.; but it is also adapted for sowing parsnips, carrots, &c., provided the seeds of the latter are properly rubbed down and mixed with sand, as is usually done. The mould-boards being attached, deep drills can be drawn for potatoes; and when one of these is removed, short dung or any of the artificial manures can be ploughed in, or the weeds on the surface buried as in ordinary digging, and in one-third of the time. All such machines are, however, better

adapted to light soils, or to ground in a high state of cultivation.

The later or principal crops should not be earthed up at all—or, if so, only to a limited extent; and for this purpose our improved cultivator with double mould-boards will be found far better than the ordinary hoe earthing-up system. If potatoes are planted 6 inches deep, they are rather injured than improved by earthing up, some say to the extent of diminishing the crop one-fourth. We have remarked in the article CARROT, p. 178, that deep-hoeing between the rows is inexpedient, as it has the effect of encouraging the lateral fibres to extend, and to induce greater growth in them, producing side roots, or what are commonly called forks. Now, the very opposite course should be pursued in the case of the potato, and every encouragement given to the side roots to extend themselves, for nearly at their extremities the tubers are formed; so that deeply stirring the ground between them tends to their extension. This process, however, must not be carried beyond a certain stage in the growth of the plants, else the extremities of the roots, which it is our object to encourage, may become seriously injured if deep-stirring takes place after they have nearly met in the spaces between the rows. This can only be ascertained upon examination. Some kinds of potatoes produce their tubers at a much greater distance

from the stem than others. These are chiefly to be found amongst the late sorts. Most of the early ones produce theirs close to the stem, or at the extremity of very short runners, seldom more than 9 inches from the stem. The blossom should be cut off as soon as it appears, for most of the evil will be effected if the process is delayed until the fruit is formed. Whatever may be said of curtailng the stems, even when they encroach on other crops, nothing but dire necessity would induce us to do anything of the kind. Cutting the haulm off entirely as soon as the plants have produced their flowers, as recommended by M. Tombelle Lomba as a remedy against the disease, has by no means been satisfactorily proved to have that effect; but it has an effect which might naturally be supposed—that of very materially diminishing the crop. If the disease is purely atmospheric, it is natural to suppose the leaves and stems would be first affected, as their office is to collect and elaborate the matter they throw into the roots and tubers; and, in doing this, they would at the same time transmit the disease along with that matter. As a natural consequence, we are bound to believe that the leaves become affected by the disease before its effects become so evident in them as to be observed by man, and hence the transmission of it to the roots must be going on before any visible symptoms appear in the leaves themselves; and if they are allowed to remain on until the plants have perfected their flowers, the roots will be as much inoculated by that time as if the leaves and stems were left on altogether. So rapid is the transmission of the disease to the tubers, that we have traced symptoms of it in them before any visible signs of it appeared in the leaves, and to such an extent in one case as led us to inquire if the disease might not originate in the soil or manure, affecting the roots first, afterwards the tubers, and lastly the stalks and leaves—reversing the generally supposed order. If, therefore, any beneficial results are to arise from cutting off the haulm at all, it must be done much sooner than has hitherto been recommended; and by doing so, the supplies will be entirely cut off, and the tubers reduced to the identical circumstances of those that are sometimes kept over a year, and buried in sand in a

dark cellar, and which are known to send out numerous immaturesly-formed potatoes from their sides, without the aid of haulm or leaves—a practice sometimes adopted to produce young potatoes during winter. No doubt the opinion laid down by Dr Lindley is quite correct, when speaking of the possibility of the tubers ripening after the haulm has been removed, *after it has arrived at a certain condition*; but before it has arrived at this condition (the season of flowering), has not the disease already been transmitted to the tubers? The rationale of his views is thus given by Mr Stephens in "The Book of the Farm," vol. ii. p. 258: "That it may be that potato tubers, after having arrived at a certain condition, possess the power of continuing their growth by their own proper and unassisted vitality; and this is rendered the more probable by the well-known fact, that the flour which gives them their principal value does not descend directly from the leaves as flour, but is in the first instance of the nature of gum, or some other fluid organisable matter, formed in the leaves and sent downwards into the tubers. Having reached the tubers, it undergoes its final change, and from a soluble substance is gradually converted by their vital force into insoluble flour. To that vital operation we have no reason to suppose that the leaves contribute: all that they do is to produce the matter out of which the tubers generate the flour. It must be observed that M. Tombelle Lomba does not cut off the stems till after flowering. It is possible that at that time the leaves of the potato have done their work as far as the tubers are concerned, and that their further duty is to nourish the tubers. If so, we have an explanation of the result of which M. Lomba so positively speaks." Not only, according to M. Lomba's assertion, is the disease arrested in its progress by cutting off the haulm, but the tubers suffer no diminution in size after the operation. This latter assertion has been by no means proved in practice, in this country at least, to be correct.

*Soil and manure.*—Potatoes succeed best on newly-reclaimed land, provided it be light and dry; and in newly-broken-up light rich loam they will succeed better without manure than with it, and, if less weighty in crop, will be of improved fla-

vour and quality. We speak of flavour and quality, or fitness for the table, and not of their chemical constituents. Mr Johnston, in "Elements of Agricultural Chemistry and Geology," p. 327, has shown that the quantity of starch is larger in potatoes which are grown upon land long in arable culture, than upon such as are newly brought into cultivation or broken up from grass. One peck of potatoes, grown upon land near Paisley, which had been almost constantly under crop for the last thirty years, produced 7 lb. of starch; while another peck, grown on a bleach-green, newly broken up, yielded only 4 lb. There is land in Cornwall, and also in Essex, that has yielded crops of potatoes annually for nearly as many years; but although the crops in both cases are both early and abundant, we have ever considered them inferior in flavour, at the table, to such as were grown from new land. In well-drained peaty soil they prosper, if not at too high an altitude. Clay soils produce waxy, and sandy soils mealy potatoes; and some soils have the property of changing the character of a variety entirely. Clay soils, in the present state of the potato disease, should be avoided. Out of 163 cases in England, 129 were returned as having suffered much by the disease. In Scotland, 16 cases escaped out of 27; but in Ireland and Wales there was scarcely an exemption from disease. Whereas in peaty soil, Mr Stephens, in "The Book of the Farm," vol. ii. p. 402, informs us, "out of 32 cases of the cultivation of the potato in moss in England, only 5 suffered much, and 17 little, while 10 escaped altogether; of 31 cases in Scotland, 9 were bad; of 41 Irish cases, only 2 suffered much, 24 little, and 15 escaped. The conclusion is—in pure, well-drained peat moss, potatoes suffer very little from disease."

In poor soils, manure must be applied, and this should be of the nature of half-decayed leaves or littering matter, to keep the ground open and dry, particularly if the soil is retentive or the locality wet. Besides, manure in the state of either of these will undergo progressive decomposition along with the growth of the crop, and become reduced to a soluble condition, in which state only manurial applications can be of any use, about the same time that the tubers are forming and

swelling, at which period the plant stands most in need of increased nourishment. Very decomposed rich manure, applied at planting the sets, may be prejudicial in more ways than one, particularly if brought into close contact with them. It cannot be of much benefit, because, by the time the plants really do require manurial assistance, this very rotten application will have become soluble and commingled with the soil. Not that in this way it is entirely lost; on the contrary, it is absorbed by the soil, and ready to be given out to the spongioles as they are formed: but unfortunately, as in general applied upon the drill-system, one-half of its fertilising ingredients descend, or are washed down perpendicularly to where it was placed; while the other half, and perhaps the most valuable—the gaseous portion—ascends upwards in a perpendicular direction also, leaving the broad spaces between the rows destitute of enrichment altogether. Necessity has long compelled the British agriculturists to adopt this mode of applying manure, because of the difficulty in obtaining a sufficient quantity to meet their extensive demand—and no doubt, for turnips and similar deep-rooting plants, the rule is unexceptionable; but the roots of potatoes take an entirely different direction in search of food from those of the turnip, carrot, mangold-wurzel, &c., for these extend downwards, and occupy a narrow line in the direction of the row; and from the fusiform character of the two last, it would be inexpedient to encourage the enlargement of any lateral fibres they might send out, as each of these would either rob the principal root, or enlarge some of the lateral fibres into side roots, and cause in them that malformation known technically as "forking." Thus manure cannot be kept too close to the roots of such plants, and therefore laying it in the drills is perfectly correct. Not so, however, with the potato, whose roots ramify in all directions horizontally in search of food, and therefore require that the ground should be equally manured all over. This plant also requires the greatest quantity of azote at the later periods of its growth, when the tubers are swelling, because they contain a much greater amount of that substance than the leaves. Manures, therefore, to be beneficial to this crop, should

be those of slow decomposition; and it is equally clear that they should be distributed equally over the ground. Vide *Preparation of the ground.*

In these opinions we are supported by Dr Madden, who, in "Prize Essays of the Highland and Agricultural Society," vol. xiii. p. 359-70, observes, "that a manure, to suit well for the potato crop, should possess the following qualities: It must be spread equally through the soil, so that the spongy, at the termination of the spreading fibres of its roots, may be supplied with nourishment. It must yield azote during the whole period of the growth of the plants—in fact, rather more is required during the later period than prior to the development of the tubers; for, from M. Boussingault's analysis, it appears that they contain five per cent more of this substance than the leaves. In an economical point of view, therefore, the best manure for potatoes would be one which contained plenty of azote, but still did not decompose very rapidly—cow-dung, for example."

Peat ashes is an excellent manure for potatoes and turnips. Their constituents are as follow:—

Silica . . . . .	32
Sulphate of lime (gypsum) . . . . .	12
Sulphate and muriate of soda (glauber and common salt) . . . . .	6
Carbonate of lime . . . . .	40
Oxide of iron . . . . .	3
Loss . . . . .	7
	—
	100

—the quantity applied, 1 lb. to the square yard, and applied in their most recent state.

Guano, if applied in a liquid state, and repeated frequently, will no doubt carry on the crop until its complete state of maturity has arrived; but the best security is to have the ground in high condition, either by large manuring for previous crops, or by trenching in plenty of cow or stable manure some time previous to planting the sets, and diffusing it equally over the whole. Salt has been beneficially applied to potato crops. On a soil of a light and sandy nature, without any manure, the return was 308 bushels of tubers per English acre; while the same extent adjoining, manured with 20 bushels of salt, gave a return of 584 bushels. Situation has also as much to do as either soil or manure in increasing the quantity of starchy matter or meanness in the tuber,

as well as securing the crop. "This starchy matter," Dr Lindley remarks ("Gard. Chron.," 1842, p. 155), "can only be formed abundantly by the action of light upon the leaves, which are the natural laboratory in which such secretions take place, and from which they are conducted by sure though hidden channels to the tubers, where they are stored up. To plant potatoes, therefore, in plantations or orchards, or under the shade of trees, is to prevent the formation of meanness which renders this plant so nutritious; and to cause the tubers to be watery and worthless."

But the potato may suffer by its own shade as much as by the shade of other plants. When its sets are planted too close, the branches shoot up and choke each other, so that the more sets are planted the smaller will be the crop of this plant. Mr Knight was the first to point out this common error, and to show that there is a certain distance at which the sets of each variety of potato should be planted, so as to insure the greatest produce. By planting too close, the plants smother each other; by planting at too great a distance, land is uselessly wasted. Practice and well-conducted experiments demonstrate what theory suggested—that the true distance at which potatoes should be set is determined by the average length of the haulm. One kind of potato is dwarf, and only grows 6 inches high; its rows should therefore only be 6 inches apart. Another kind grows 3 feet high, and its rows should be 3 feet asunder. The space from set to set in the row appears to be immaterial; 6 or 8 inches is sufficient for those which grow 2 feet high. An experiment, made in the gardens of the Horticultural Society of London, "showed that the early champion, a sort whose stems are on an average 2 feet long, was planted in rows 2 feet 6 inches apart; the produce was 15 tons 19 cwt. 82 lb. net per acre," or, in round numbers, 16 tons; "while, by reducing the distance between the rows to 2 feet, the produce was increased to 24 tons; but, by diminishing it still farther to 1 foot 6 inches, the produce was reduced to 22 tons 16 cwt. 102 lb.; and where the rows were only 6 inches apart, the produce fell to 16 tons 17 cwt. 110 lb. Such an experiment seems conclusive."

As regards manure for potatoes, the

inference is, that, under all circumstances, two crops, manured with guano, have been saved out of three; that, if applied to autumn and early spring-planted crops, it is advantageous, but that it is dangerous in late planting. The conclusion arrived at in the use of farmyard manure is, that if used abundantly in a very rank condition, and especially if applied in this state to late-planted crops, it is an extremely disadvantageous application. Ashes are a safe manure when applied by themselves, and crops have suffered little or nothing by disease throughout Britain when manured with them alone, in the proportion of 27 to 4; and, when mixed with farmyard dung, the success has been as 54 to 15—or that is, in the former case, 4 suffered much, while 27 suffered little or nothing; and in the latter, 15 suffered much, while 54 nearly escaped. Saline manures have not been productive of injury, and are perhaps beneficial. Without manure, the results are favourable as regards the disease. In England, 32 cases suffered much for 96 which escaped; in Scotland, 1 suffered for 11 that escaped; in Ireland, 1 for 7; and in Wales, 1 for 2—the whole giving 35 cases of suffering for 116 which escaped. Nothing is discernible in favour of salt; nor does sea-weed indicate a better effect. The conclusion of the whole matter may thus be summed up—That over-luxuriance, arising from whatever cause, was highly favourable to the progress of disease, and *vice versa*.

*Forcing*.—The true ash-leaved kidney, Jackson's improved kidney, British queen, early ten-weeks, Soden's early Oxford, early Manly, golden dwarf, and others of a like early description, should be chosen for this purpose, selecting whole tubers of medium size, and placing them close together, either in shallow boxes filled with light rich sandy soil, or on the borders of an early peach-house or vinery; or, better still, among half-decayed leaves placed on the surface of a moderate hot-bed, one light of which will be sufficient space to excite a sufficient number of sets to plant a pit of 15 or 18 sashes—that is, nearly 100 feet in length—of a 6-foot pit. The genial heat from the leaves below will gradually excite the tubers (but on no account must the process be hurried, for too rapid excitement would cause an undue excitability in the sap, and greatly weaken the embryo shoots), while the humidity arising from the leaves below will prevent any loss taking place in the juices of the plant by unnecessary evaporation, the young roots of which will strike into the partially decayed leaves which will adhere to them, and

render their removal a safe and easy matter. When the shoots have attained the height of 3 inches, they should be transplanted into a light soil, laid 4 inches in thickness on the surface of a bed of dung and leaves, in a slight state of fermentation. We do not usually, unless the heat is rather strong, cover the whole surface of the bed at once with soil, but only lay it in ridges across, about a foot apart, centre from centre, and on these set the plants, filling up the intervening spaces afterwards as the heat of the bed declines, and as the roots extend. By this means the heat from the bed has free means of ascending upwards to warm the atmosphere of the pit. The plants are set 4 inches apart in the lines. It should be remarked, that a very slight excess of bottom-heat is very prejudicial to this plant, causing them to become, in a few days, drawn up, slender, and etiolated in colour; and the same bad effect is produced by a deficiency of ventilation. At the same time, cold must be excluded, for few plants suffer sooner by frost than this; covering the glasses nightly with felt, or wooden shutters made to fit the sashes over which they are to be placed (*vide* fig. 789, and Sect. 5, ON COVERING THE ROOFS OF GLASS-HOUSES AND PITS, FOR THE EXCLUSION OF COLD OR THE RETENTION OF HEAT, &c., vol. i. p. 551), is a much better precaution than employing extra heat in the bed.

Although we have mentioned a bed of fermenting material, we do so, not that it is better than, or even so convenient as, growing them in a tanked pit (of which figs. 629, 631, and 632, vol. i. pp. 450, 451, may be referred to as examples), which of all other modes is the best for all sorts of kitchen-garden productions required at an unseasonable period of the year. Indeed, for all such purposes we expect to see the day when long narrow borders shall be constructed, with vaults under them, and these heated with hot-water pipes, or having tanks of water circulating under them. In such cases, all that is required is an extent of common frames and sashes to be placed over them, to cover in the whole surface. In such borders, most of the productions of the kitchen-garden may be brought to great maturity. Beds of fermenting material can only be advantageously employed when abundance of leaves is conveniently to be had, or where tanners' bark can be got for little less than carting away. Either to purchase such material, or to employ stableyard manure, would be a much more extravagant process than even that of tanking or vaulting the border, as noticed above. The results never can be so satisfactory, on account of the uncertainty of heat, and the unnecessary amount of labour. Where there are extensive lawns to keep in order, or where the rotting down of tree-leaves is carried on—for the purpose either of converting them into manure, or employing them, when thoroughly reduced, and mixed with sharp river-sand, as a substitute for peat-earth for American plants—then advantage may be taken of the process of fermentation, and potatoes, pease, asparagus, lettuces, &c., all requiring very little heat, may be grown upon the masses. In this way we employ leaves to a great extent. As they are gathered from the lawns and drives, they are

carried to an enclosed place, well exposed to the sun, and shut out from general view, and made up into a mass 12 or 15 feet in breadth, 50 or more feet in length, and 4 feet in height. When hard trodden down, a fine genial fermentation takes place. This mass is covered with frames and sashes, and soil is laid on the surface of the leaves to the depth of 6 inches: on this the tubers of potatoes, when sprung a few inches high, are planted, pease sown, lettuce planted, and the full-grown roots of asparagus set. The lights are put on, and in cold weather are covered with felt shutters of a size corresponding to that of the glass sashes. In such large masses a pretty uniform heat is maintained without the aid of linings; and all the labour attending the process of culture consists in ventilating, on all favourable occasions, protecting in cold weather by covering, and planting or sowing for successional crops. Potatoes may be placed in a slight heat, in front of a vinery or similar place, when the young shoots are sprung to the length of 3 or 4 inches; or a better system is, when the young roots have made 2 or 3 inches' progress, to separate the plant from the tuber, and plant them in the beds as above. Examine the soil at the roots frequently, to see that they do not suffer from a deficiency of moisture, as leaves, during fermentation, give out a much less amount of vapour than stable-yard manure does; and if a proper degree of humidity is not kept up at the roots, the crop will be scanty and inferior in quality. When the potatoes have fairly established themselves, and their roots begin to appear on the surface, lay in between the rows 3 inches of dry fine soil, that has been kept for some time under cover, choosing a fine warm day for the purpose.

Forcing potatoes in pots was successfully practised by the late T. A. Knight, Esq., the essence of whose practice is to the following effect: At the season when the general crop of early potatoes is ripe, and in the process of being taken up, select tubers having perfect eyes, and plant them in 6-inch pots, one tuber in a pot. Bury the pots in the ground till they are required for planting; during this period, the excitability of the plants is not at all expended on account of the low temperature at which they vegetate, and therefore, when plunged in the hot-bed, they instantly shoot with very great rapidity, and in a few days begin to generate tubers. One stem alone should be suffered to grow in each pot; for where more remain, the tubers are smaller, and the entire crop is not increased in weight. The embryo shoots should be rubbed off as they appear. When the plants grow in small pots, the gardener will have apparently the advantage of being able to take out the largest potatoes, by inverting the pots, without materially injuring the fibrous roots; but this will rarely be found possible in practice, because the plants, having the range of their roots confined to the limits of the pots, soon occupy the whole of their pasture, and therefore do not produce their tubers in succession, as they will under ordinary circumstances. Mr Knight confined his plants, (which were naturally of a very dwarfish growth), to small pots, because, under this mode of cul-

ture, the tubers reach maturity sooner, and are superior in quality: but the crop is not so heavy as where the roots are permitted to extend more widely; and, therefore, where a larger but rather later crop is required, the best plan is to place the tubers in small pots to vegetate, and from these to remove them, with their roots and germs uninjured, to the hot-bed. "I tried," says this great experimentalist, "the effect of placing a few tubers on the floor of my cellar, disposing them just in contact with each other, and as soon as the germs were about 4 inches long, a hot-bed was made to receive them. This experiment succeeded perfectly; and as it is not attended with so much expense and trouble as either of the preceding methods, it will be found, in most cases, the most eligible. All that appears necessary to obtain an early crop is to advance the growth of the plant as much as convenient under a low temperature, so as to avoid all unnecessary expenditure of its excitability, and consequently to preserve its germs and roots, as much as possible, uninjured by transplantation." We have long grown the potato in pots, and with sufficient success; but we would always recommend the tubers being planted in the pots as soon as they are ripe. By this process, the slow and gradual vegetation is brought into action, and the pots can be placed in any out-of-the-way place until the young shoots begin to appear above the ground, at which period, for reasons that require no explanation, they should be placed in a light and airy situation. Some will vegetate sooner than others, and those that do so should be first removed to the light; and a better place for them cannot be found than a cool pit covered with glass, or suspended shelves placed near the top of a vinery or peach-house, but always where frost cannot reach them. This slow process of germination is admirably adapted for those that are to be placed in a little higher temperature towards the end of January or middle of February, or even later; but for those intended to be excited by the end of November or middle of December, a little more heat will be required than that stated above. Of course, a crop thus early produced can never be expected to be so good as one produced later in the season. It is, however, a good plan to have all the tubers intended for forcing planted in pots, or laid on a floor, as Knight has recommended, and to draw from that stock crop after crop as they are to follow in succession.

The London market-garden practice for forcing early potatoes is thus detailed by Mr Cuthill in his work already quoted: "When potatoes are wanted early, a long bed 5 feet wide is dug out to the depth of 2 feet. This trench is filled with hot dung, on which 6 inches deep of the surrounding mould is put. Middle-sized whole potatoes are used for planting: they are placed in close succession along the bed, covered with 2 inches of mould, hooped, and covered over with mats and straw. In about a month they will have sprouted; frames are then got ready, placing 2 feet of hot manure along the whole line of framing, which is sometimes 100 yards in length; the mould is put on to the depth of 8 inches; the potatoes are carefully taken up

from the striking-bed, all shoots are removed except the main one, and they are planted 4 inches deep. Radishes are then sown thinly over them, covering lightly with mould. When the haulm of the potato has grown to about 6 inches in height, the points are nipped off: this is done in order to give the radishes fair play; and although it may stop the growth for a few days, still the crop is always excellent. The plants are never moulded up, a plan which weakens the potato more than anything else. After planting, nothing more is required but to admit plenty of air, and give water," and, of course, exclude frost: "the crop is not dug up until it has come to maturity." Potatoes are also largely grown in hooped beds in the open ground, the tubers being sprouted as above described. "The beds or ridges are dug out 2 feet deep in January, filled with hot dung, and covered with the surrounding mould to the depth of 10 inches. The potatoes are taken up and planted 5 inches deep, and above all radishes are sown. The ridges are then hooped over, allowing about 2 feet of space in the middle between the mould and the hoop. They are covered with mats and straw; but, as soon as the radish has come up, they are uncovered daily, and covered again every night. This is continued till the potatoes are ready for digging in May; for sometimes large losses are occasioned by a sudden change of weather on cold April nights." As regards the sorts grown for early forcing, our authority also states that Mr Fitch, a very extensive grower at Fulham, cultivates the true early shaw: many grow the ash-leaved kidney, because it always fetches the highest price; while Mr Cuthill himself prefers the lapstone kidney, as being the best flavoured, most mealy and productive. This variety is a great favourite with us; but we have not found it so good for forcing as the ash-leaved kidney and golden dwarf.

The following deception is common in the early-potato trade: The old tubers of the Cornwall kidneys are kept back till July, and then planted. "They grow fast, but the crop never ripens before frost sets in; as soon as the haulm is cut down, large quantities of straw are put on the ground, and towards Christmas the tubers are dug up, put into 1-lb. and 2-lb. baskets, and sold for new potatoes at from 6d. to 8d. per lb." They are full of water and tasteless, and the skin remains firmly attached; and, when cooked, they have very little resemblance to new potatoes, except in size and external appearance. The substitution of immaturely-ripened potatoes—of a variety known as the Dutch winter potatoes, for early-forced ones—is largely practised in Covent Garden market. Twenty-five years ago, we had these potatoes sent from Holland, with instructions to plant in autumn in the open ground, and statement that they would grow all winter, and be fit for use early in spring. The result was, that the tubers came into use exactly at the same time as did those of the ash-leaved kidney and several others planted in March. This is a small round potato, with a very uniform outline and smooth skin, by no means uncommon in the vegetable mar-

kets abroad as one of their ordinary sorts. If the old tubers be kept back till July and then planted, an abundant crop of immaturely-formed young tubers will be found at the roots; and, if kept in the ground till they are required, they have all the external appearance of fine forced potatoes, but not one of their qualities.

Young potatoes, during winter, are produced by selecting the largest tubers of almost any variety in spring, placing them in a cool cellar to retard vegetation. The embryo sprouts as they appear are rubbed off until the month of August or September, when they are removed to a warmer place—the floor of a mushroom-house, for example. Here they are laid upon a bed of light sandy soil, about 10 inches apart from each other; they are then covered over with similar soil 4 or 5 inches deep, watered with tepid water, and allowed to remain so till December, at which time numbers of young potatoes will be found attached to the old tubers by a transformation of the matter in the latter into young potatoes, and this without the production of stems or leaves. They may, for the same purpose, be packed in soil in old casks, boxes, or, indeed, anything that will keep the soil together; and they may be placed in any out-of-the-way place, if in a temperature of from 50° to 60°.

*Taking the crop, and subsequent preservation.*—The early varieties are taken up for use as they attain the required size, which, in warm exposures, will be about the beginning of June, and so on till the middle of July in less favourable places. Some remove the soil partially from about the roots, and gather the largest tubers, leaving the smaller ones for a week or so longer, in the expectation of their attaining a larger size. It is seldom, however, that this mode of proceeding realises the hopes of the grower, for the potato, if once disturbed at the roots, seldom recovers the check. It is, therefore, better to take up the crop as it is required, and immediately replant the ground with something else. For private use, only as many should be taken up daily as may be required for that day, as they will not keep good above a day or two; and hence the inferior quality of those young potatoes brought to the London markets from the Continent, compared with those grown in the vicinity. The end of May in England, and the beginning of June in favoured spots in Scotland, is the commencement of potato-taking; while, on less favoured situations, it is delayed till the beginning of July, even where partially protected. A week's delay in commencing on the crop is of much importance to the bulk and

quality, for at those periods, particularly if the weather is warm, and accompanied with "May showers," the young tubers swell amazingly fast. In July, August, and September, they will be in fine condition for family use. Those intended for seed should be gone over, and if any spurious ones have crept in by accident, they had better be removed, as they will be readily distinguished by their haulm from the others. When the foliage of these begins to decay they may be lifted, so that the ground may be cropped with something else; and if they are buried in a deep pit, in a dry yet cool shady place, they will require no further care till the season of planting arrives. Care, however, must be taken that they are not laid in too great quantities together, for fear of their heating; and also that each sort be kept separate and correctly named, to prevent confusion at planting time.

Late varieties constitute the great bulk of crop, and are those which require most care in taking up and storing. So long as the haulm continues green, the potato should be allowed to remain in the ground, as this is quite indicative that the tubers have not arrived at full ripened maturity, which again is indicated when the haulm begins to wither and die off. This is an important point in their management, so far, at least, as relates to those intended for the table, in which flouriness (or starch) cannot too much abound; and unless fully ripened, that conversion cannot properly take place. The art of keeping potatoes (if really free from the disease) is founded upon sufficiently correct principles, the leading point of which is exclusion from light; for if this is not attended to, they not only become injured in their nutritious qualities, but are actually rendered poisonous when allowed to become of a green colour, which they readily will do if exposed to light—and this the sooner, if vegetation is in the least excited. Keeping them in potato-houses, therefore, unless so constructed as to exclude light, must be considered injurious to them. In this state of darkness they should be placed the very day they are taken out of the ground; and it were better that they were stored by in rather a damp state, than that they should be exposed for a day to the light with a view to dry them. Drying has a bad

effect on the skin of the potato, for if subjected to this, the skin and part of the epidermis are made to part with their natural juices, which ever afterwards renders them incapable of absorbing moisture, even if presented to them. Fermentation is an important evil to guard against, as it changes the whole substance of the tuber, and, so far as seed-potatoes are concerned, destroys their vegetative principle. To guard against this, they should be placed in small quantities together, in long narrow ridges with partitions of earth between them, dividing the whole into compartments of a size such as will probably be sufficient to supply the wants of the owner for a week or so at a time. Potatoes once dried should never be again wetted until they are going to be used. Straw or any other littering matter is an objectionable covering for potatoes, for by its decomposition carburetted hydrogen is formed, and mixes more readily amongst the potatoes in the heap than it escapes through the soil laid over it. The greatest care should be taken that all tubers bruised or cut during the operation of lifting should be kept by themselves for immediate use; and were it not that potato-lifters would think us far too fastidious, we would say every one whose skin is broken should be rejected also, with the same care and upon the same principle that all apples bruised at gathering are kept apart from those sound ones carried to the fruit-room.

Keeping potatoes has the effect of diminishing the quantity of starch in them; those in October, according to Mr Johnston (in "Agricultural Chemistry and Geology," p. 329), which yielded readily 17 per cent of starch, gave in the following April only  $14\frac{1}{2}$  per cent. The effect of frost is also to lessen the quantity of starch. It acts chiefly upon the vascular and albuminous part, but it also converts a portion of the starch into sugar—hence the sweetish taste of frosted potatoes.

The housing of potatoes, unless such quantities as are required for immediate use, is exceedingly wrong in principle, as is also the manner in which many are carelessly pitted out of doors. The points to be kept in view are, a dry airy exposed situation, having a northern exposure and perfectly dry below, and piling the potatoes on a smooth level surface not lower

than the surrounding soil, in long narrow ridges 3 feet on the base and 2 feet in the perpendicular, the sorts to be kept separate with earthen partitions as stated above. It is better to pile the whole stock in one or two long ridges than to have a dozen of small conical ones scattered about, and from which the frost and heat are seldom properly excluded. We prefer the floor of the pit to be level with the surface, to prevent the chance of damp; and also having the whole stock in one place for convenience of covering, turning over if need be, and for taking out as required. If the tubers are stored when very wet, and fears arise on this head, a row of drain-tiles may be laid along the floor under the potatoes open at both ends, but secured against the intrusion of mice or rats by placing a fine wire covering over their orifices. A tile-pipe or two may be placed with a like precaution, communicating with them, and passing like a small chimney through the top of the pit. During winter, these may be all left open for the circulation of air; but by the beginning of February they should be completely stopped up, to prevent the entrance of heated air from without: at that time all danger from fermentation will have ceased. Where turf can be got conveniently, a course of it, with the *green side uppermost*, may be laid over the tubers, but no littering matter whatever; and if turf cannot be conveniently got, lay the soil on at once. The object of covering is twofold—first, to exclude frost and wet; and secondly, to exclude heat: now earth, although no bad non-conductor of heat or cold, is not sufficient of itself to answer our purpose; therefore, after 9 or 10 inches of soil are laid on, thatch the whole over 1½ feet in thickness with straw, fern, heath, or any similar non-conducting material. This is more particularly necessary with those that are to be kept till a late period in the spring, to last till new potatoes come in, which cannot be kept at too low a temperature. With the general stock, all that is required is to exclude wet and frost, therefore the thatching need not be so thick. In storing late potatoes for spring, use the principle of the ice-stack (figs. 720, 721); and what has been said regarding the keeping of ice (vol. i., Section ICE-HOUSE) should be strictly kept in view.

*Approved sorts and their qualities.*—Potatoes are divided by cultivators into early and late sorts. The names, we should observe, are very arbitrary, most localities having their favourite sorts, and consequently their own names. An extended list would, therefore, be of little general utility, more especially in the present unhealthy state of the plant. We will, therefore, confine ourselves to the best of the early and second early varieties (which for the most part constitute the garden sorts), the names of which are more permanent.

*Ash-leaved kidney.*—One of the most popular sorts for forcing, and also for the earliest crop in the open borders. It fetches a better price in the market than any other, is exceedingly thin-skinned, of good form, and with few eyes. Should be planted whole, with the end containing the eyes uppermost; or, if cut, the incision should be made lengthways through the centre.

*Jackson's improved ash-leaved kidney.*—A selected variety from the last, of larger size, greater hardiness, and a more productive bearer. Not quite so early as the last, and, being better set with eyes, is much less liable to remain in the ground without springing: an excellent sort.

*British queen.*—A round potato of dwarf and prolific habit; one of the earliest.

*Soden's early Oxford.*—A round potato of recent origin; very early, and well adapted for forcing.

*Fox's seedling.*—A popular early potato about London, either for forcing, or for earliest crops in the open air. There appears little difference between this variety and that of early Manley and early Cockney. Tubers round, white, rather waxy.

*Early frame* and *early ten-weeks* are very similar. Indeed, any of the last five sorts may be grown with advantage, particularly for forcing, and the earliest border crops.

*Jackson's golden drop.*—Very dwarf in haulm, of good quality, and well adapted for forcing. Skin tender, and a productive cropper.

*Rufford kidney.*—A long-famed Lancashire variety, not in very general cultivation elsewhere. It is a very early variety, mealy, well-flavoured, and stands the frost better than any other early sort. It is also known as the lady's finger.

The most comprehensive as well as the best descriptive lists of potatoes, are those published by Messrs Peter Lawson and Son, the eminent nurserymen and seedsmen, Edinburgh, first in their "Agriculturist's Manual" some years ago, and more recently in their "Vegetable Products of Scotland," a work of much research and great accuracy, invaluable both to the gardener and farmer. These lists are rendered valuable, as they comprise all the known varieties, with clear descriptions "as to the habit of growth, nature and colour of foliage and flower; the shape and colour of the tubers, and peculiarities of the skin; with general remarks as to their use and comparative value for the table;"—forming a very safe guide, from which the cultivator may select suitable varieties, and reject such as may appear unadapted to his soil, or which, for other reasons, may seem unworthy of culture.

From the last of these works we have made the following selection, omitting, however, all

such as are described as unhealthy, or of second-ary merit:—

“*Earliest garden sorts adapted for forcing, on account of their dwarf habit of growth.*—*Early frame, common.*—Stem slightly reclined; about 1½ feet high; tuber medium-sized, and round; colour whitish and roughish; mealy, good flavour, and healthy.

“*Fox's early delight.*—Stem growing upright; about 1½ feet high; tuber slightly hollow at the end, of a roundish shape; colour whitish, and slightly rough-netted like; mealy, superior flavour, and healthy.

“*Fox's early globe.*—Stem slender and reclining; about 1 foot high; tuber round, and few-eyed; colour whitish, slightly rough, and netted-like; mealy, good flavour, and healthy.

“*Fox's John Bull, or early kidney.*—Stem slender and reclining; about 1½ feet high; tuber long, nearly uniform thickness; colour whitish, and smooth; pretty mealy, good flavour, and healthy.

“*London dwarf kidney.*—Stem slender and reclining; about 1 foot high; tuber flat, thickest near the point; eyes prominent; colour whitish, and smooth; waxy at small end; indifferent flavour, and healthy.

“*Williamson's favourite.*—Stem slender and reclining; about 1½ feet high; tuber slightly elongated; colour whitish, and smooth; mealy, good flavour, and healthy.

“*Earliest garden potatoes, not so well adapted for forcing as the preceding, on account of their taller habit of growth.*—*Ash-leaved early.*—Stem upright and loose; about 1¾ feet high; tuber roundish; colour whitish, and roughish; medium flavour, but healthy.

“*Chapman's early kidney.*—Medium between the ash-leaved and July kidney; resembles the latter in form.

“*Early seedling.*—Stem slender and straggling; about 2 feet high; tuber round, few-eyed; colour whitish, and smooth; mealy, superior flavour, and very healthy.

“*Hopetown early.*—Stem strong and upright; about 2 feet high; tuber large, round, with few eyes; colour dull white, rough, and netted-like; mealy, good flavour, and very healthy. Perhaps the most superior variety in the class to which it belongs.

“*Invermay early.*—Stem spreading; about 1¾ feet high; tuber round; colour very white, and smooth; mealy, good flavoured, and very healthy.

“*Kay's early American.*—Stem slender and spreading; about 1½ feet high; tuber slightly oblong and flattish; colour light red, and roughish; mealy, medium flavour, and very healthy.

“*London particular.*—Stem rather upright and compact; about 2 feet high; tuber round, or slightly elongated; colour whitish, and roughish; medium, good flavour, and very healthy.

“*Main's particoloured seedling.*—Resembles the ash-leaved kidney in form, but rather larger, and the round end of a deep purple colour. Raised in 1850.

“*Musgrove's snow white.*—Stem rather upright and compact, about 2 feet high; tuber round,

hollow at the point; colour remarkably white, rough, and netted; medium, good flavour, and very healthy.

“*Second early garden potatoes.*—*Caracas.*—A late, prolific, and healthy growing sort; of superior quality; roundish, slightly flattened shape; reddish colour, and rather under the medium size. It was found wild in Caracas. This variety is also known by the names of the American and the Prince-regent potato.

“*Dwarf American early.*—Stem pretty upright, about 1 foot high; tuber slightly flattened; colour white, and rough; mealy, good flavour, and pretty healthy.

“*Early Wellington.*—Stem slender and spreading, about 1½ feet high; tuber round; colour yellowish white, and very rough; mealy, good flavour, and very healthy.

“*Gold-finder.*—A very tall, luxuriant-growing, and productive variety, with white, slightly oblong, and somewhat flattened tubers; reputed as being of superior quality, and yielding a good crop, even on inferior soils, and with little manure.

“*Lawhead early red.*—Stem slender and spreading, about 2 feet high; tuber very round; colour dark red, and roughish; mealy, good flavour, and healthy.

“*Lawhead early white.*—Stem rather slender and spreading, about 1½ feet high; tuber rather large; colour whitish, very rough, and netted; mealy, good flavour, and pretty healthy.

“*Lawson's conqueror.*—Very similar to Peffermill prolific, but tubers generally of a larger size.

“*Matchless kidney.*—Stem upright and compact, about 1½ feet high; tuber oblong; eyes few and prominent; colour white, and smooth; mealy, superior flavour, and medium healthy.

“*New early Windsor seedling.*—Stem rather slender and spreading, about 1½ feet high; tuber round; colour white, and smoothish; mealy, good flavour, and very healthy; of excellent quality, being dry, mealy, and of an agreeable flavour, and very prolific.

“*Painted lady, early.*—Stem upright and compact, about 1½ feet high; tuber irregularly round; colour white and reddish; rather waxy, flavour medium, and healthy.

“*Peffermill prolific.*—Medium-sized; skin roughish; eyes deep; roundish shape, inclining to a flattened oblong; colour buffish white.

“*Prince of Wales' early.*—Stem strong and upright, about 2 feet high; tuber large, slightly oblong, and flat; colour white, and smooth; rather mealy, good flavour, and very healthy.

“*Prince Regent.*—The commonest white potato in the Scotch market; similar as to quality, but rounder in shape than the Peffermill prolific.

“*Ross's pigma kidney.*—Stem spreading, about 1 foot high; tuber small, long, crooked, and few-eyed; colour whitish, and roughish; mealy, superior flavour, and medium healthy.

“*Rough Robs.*—The potato to which this name has been applied is a healthy-growing and prolific second early, roundish shaped, slightly flattened, and reddish coloured; rough-skinned tubers; and is much esteemed in the lower part of Argyllshire and neighbouring districts, for the purpose of succeeding the earlier white sorts.

*“Seek-no-farther.”*—Stem compact and bushy, about 1½ feet high; tuber round; colour white, rough, and slightly netted; mealy, good flavour, and healthy.

*“Smith’s yellow Peruvian.”*—Tubers rather under the medium size; roundish, or slightly elongated, with numerous deeply-sunk eyes, and of a yellowish-white colour. This is a healthy-growing and superior late sort, having a peculiar yellow-coloured flesh; received from its native country, Peru.

*“Tall American early.”*—Stem strong and pretty upright, about 2 feet high; tuber flattened; colour very white, and rough; mealy, good flavour, and very healthy.

*“Taylor’s forty-fold.”*—Stems slender and spreading, about 1½ feet high; tuber oval, and much flattened; colour rough and dull reddish; mealy, superior flavour, and very healthy.

*“White Sutherland kidney.”*—Stem very upright and compact, about 1½ feet high; tuber curved, flat, and small towards the stalk; colour whitish, rough, and netted; mealy, good flavour, and healthy.”

The number of potatoes described in Messrs Lawsons’ work is 175; and as the whole have been grown in their extensive experimental grounds, and their conditions carefully recorded by competent persons, we consider their list as the best data in existence by which their respective merits may be calculated. The garden varieties extend to fifty-eight in number, and from these our selection has been made.

The nomenclature adopted above is that by which the varieties of potato are best known in Scotland; but an examination of the models of them, now in the Botanical Museum in the Royal Gardens at Kew, will enable those interested to recognise the sorts, although presented to them under new names.

*Second earlies.*—*Early Shaw*, or *Shaw’s early*, a variety grown extensively by the London market-gardeners for forcing, to come to market in May. It is, for an early sort, a large, beautiful, oblong, white-skinned potato, whose only fault is its hollow eyes. It is very productive.

*American early.*—One of the most valuable potatoes ever grown. How long it has been in cultivation we have no knowledge, farther than it was well known to us fifty years ago. It has always maintained a good position in the estimation of cultivators, being very productive, of medium and uniform size, and of excellent quality from August till the following spring. It has resisted the epidemic better than any other sort. Round, yellowish white, very flowery at an early stage.

*Fifty-fold.*—A most extraordinary cropper; tubers not very large, of uniform size, and keep well.

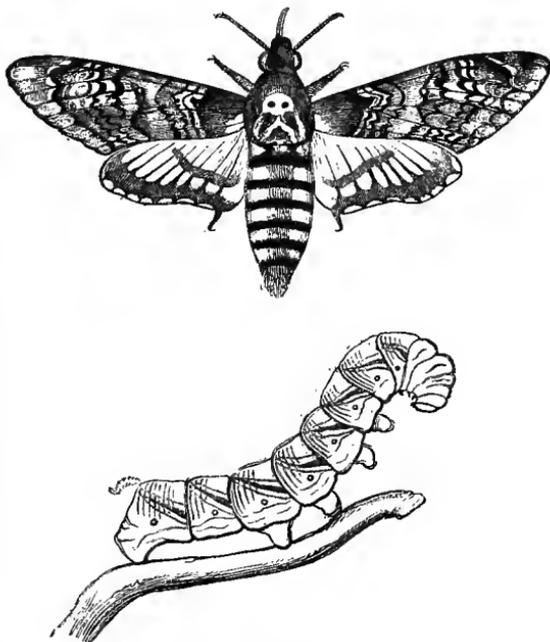

*Early champion.*—Tubers large, round, white; very prolific, and in high estimation in the London market.

*Lapstone kidney.*—Decidedly the best kidney-potato grown; an excellent cropper; tubers sometimes 7 inches in length and 3 in breadth. We have remarked of this sort, that it is longer in coming through the ground in spring than most others; and the stems at first appear weakly, but they soon lose this appearance, and grow most vigorously. It is a first-rate potato for the table in August and September, and will keep in excellent condition till May following, without losing either its mealiness or flavour. It is of Yorkshire origin, said to have been raised by a cobbler, and hence the name. Many of the late varieties, which were for a time popular, have disappeared, and others are yearly coming into notice—a circumstance easily accounted for, seeing how freely the potato is reared from seed. A catalogue of sorts was published in 1842 by Mr Chatwin, enumerating and describing above 150 varieties. On the Continent the sorts are innumerable, but chiefly small, as the potato is there regarded more as an article of food for man than for the inferior animals.

The last five sorts are chiefly of English origin, or cultivated more largely there than in Scotland. They are not included in Messrs Lawsons’ descriptive lists.

*Insects and diseases.*—The *Aphis vastator* is frequently found on the leaves of the plants; but so far from its being the cause of the disease, as asserted by Mr Smee, it is seldom found upon them in sufficient numbers to produce much effect. The larva of *Noctua exclamatoris* (the heart-and-dart moth, fig. 71) is far more destruc-

Fig. 93.

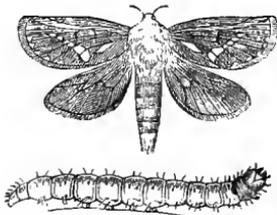

DEATH'S-HEAD MOTH AND CATERPILLAR.  
Half natural size.

tive. It attacks the haulm just under the surface of the soil, and perforates right through it, and not unfrequently cuts it asunder. It also attacks the tubers, and may often be detected in them at taking-up time. The wire-worm or click-beetles, of which no fewer than sixty species occur in Britain, in their larva state, often attack the tubers; of the larvæ of *Cataphagus lineatus*, fig. 19, we have found as many as forty-seven attached to one moderate-sized potato. Their presence in soils cropped with autumn-planted potatoes we dread much more than frost, or any other evil that could befall the sets. *C. obscurus* is most abundant in Scotland, and although we are not deficient in any of the Elateridæ tribe, still it seems to be the most destructive. The caterpillar of that beautiful and rare insect, the death's-head hawk-moth (fig. 93), is sometimes found on the stems of potatoes, but not to such an extent as to inflict very great injury.

The caterpillar of *Hepialus lupulinus* (the garden swift) is often destructive to the potato.

Fig. 94.

GARDEN SWIFT AND CATERPILLAR.  
Natural size.

"The moth, usually, is chalky brown, head and thorax woolly, and its upper wings dark-brown, with a broad line of white; but sometimes this is absent, and at other times the upperwings are chalky

white. These moths appear about the end of May, and are very abundant in the evening in meadows and other grassy places. They deposit their eggs apparently indiscriminately, which soon hatch, and the caterpillars produced are cylindrical and yellowish white, with black dots and hairs on the upper part and sides of their segments. The caterpillar changes to an ochreous shining cylindrical pupa." — *Gardeners' Chronicle*. In the latter state it is often very destructive to potato roots.

The curl, which committed no small devastation on the potato crops some years ago, is now little heard of. Opinions as to its cause, and the remedies proposed, were both about as conflicting as those of the present more fatal epidemic. The cause of the scab or ulcers on the skin of the potatoes has been as little understood as either—some attributing it to the manures applied, and others to certain ingredients in the soil. It is now less heard of; superior cultivation has probably effected, so far, a cure in this case. The rook is gravely charged with making free with our seed-potatoes as soon as they are planted, and also helping himself to a few full-grown ones in autumn. We believe, if the matter were investigated by even a less enthusiastic ornithologist than Mr Charles Waterton, that it would be found the seed-potatoes purloined, in most cases, are infested with wire-worms, which are attracted to the sets as soon as they are placed in the ground. We have

long ago satisfied ourselves upon this point, and will never kill one of these birds; but those that are sceptical may do so, and on dissecting the maw they will find abundant evidence as to this point in the numbers of wire-worms contained in it. It is possible that, during the short period of incubation, hunger may drive them to steal a few sets, but it is searching for the wire-worm more than the potato that leads them to the newly-planted fields. The important services the rook performs to man in the destruction of his more-to-be-dreaded enemies are so great, that they should be admitted as evidence to character when he is arraigned at the bar of vulgar prejudice.

Nothing like a correct opinion, we believe, can be offered regarding the cause of the disease which has for some years more or less been disastrous to the potato crop. All, therefore, that can be done, in our present state of knowledge on the subject, is to apply the best remedies we can. Our own opinion has all along been in favour of autumnal planting, not as an infallible remedy by any means, but as one of very considerable mitigation. Nor are we alone in holding this opinion. Out of sixty-four returns furnished by various individuals throughout England and Wales of the state of the general crop of 1849, fifty-three were in favour of autumnal planting, while only eleven were against it. In England, those planted in autumn were by the same report stated to be better, in the proportion of thirteen to eleven, than those planted in January and February; and had these reports extended to May—for even to that late period do some people delay the finishing of their potato planting—the difference in favour of autumnal planting would have even been much greater.

*General remarks.*—The potato appears to change its character by change of climate or circumstances. Most of the Scotch and Irish varieties degenerate when removed to England, and often when removed from one district of the same country to another. They soon degenerate when taken to the West Indies; and although cultivated by our countrymen in many parts of the East Indies, where they yield good crops, yet are they deficient in that flavour peculiar to them in Britain. The most extraordinary change of character we recollect of is that recorded by Phillips, on the authority of Samuel Bate, Esq., who went with the first settlers to Van Diemen's Land. He took out about half a bushel of potatoes for seed, which were all of one kind; but to his great surprise, when they were dug up, he had five distinct varieties—viz., the white champion, the round red, the kidney, a small round potato, and the variety commonly called the miller's thumb. A sample of each of these was afterwards sent into a warmer climate, where, on being planted, they all degenerated into one, the original variety!

"The best rules to obtain and preserve sound potatoes and a good crop are—1. Grow none but those which ripen by August; 2. Plant whole middle-sized potatoes; 3. Plant on moderately-light soil, manured some months previously; 4. Apply no manure at the time of

planting; 5. Plant in November, in light dry soils, but not until February in wet soils; 6. Preserve seed-potatoes between layers of earth until required; 7. Plant as you dig—that is, dig enough for one row, and then plant it with the dibber, so as to avoid trampling on the ground.” Why not plant in the trench as the digging goes on? “8. Let the tops of the sets be 6 inches below the surface; 9. Do not earth up the stems; 10. Do not cut down the stems; 11. Take up the crop as soon as the leaves begin to look yellow, in July or early in August; 12. Store in a dry shed between layers of earth, sand, or coal-ashes.”—*Cottage Gardeners' Dictionary*, p. 741.

The European names are, Pomme de Terre in French; Tartufi bianchi, or Pomo di Terra, in Italian; Kartoffel in German; Batata da Terra in Portuguese; Aardappel in Dutch; and Batatas Inglezas in Spanish.

#### § 4.—THE JERUSALEM ARTICHOKE.

*Natural history.*—The Jerusalem artichoke (*Helianthus tuberosus* L.) belongs to the natural order Compositæ, sub-order Heliantheæ, and to the class Syngenesia and order Frustranea. The generic name is derived from *Helios*, sun, and *Anthos*, a flower, from the resemblance of the flowers of the genus to that luminary, which they are supposed to look towards while the earth is illuminated by his light. The popular name Jerusalem is merely a corruption of its Italian name *Girasole*, and artichoke is derived from the resemblance in flavour which the tubers have to the bottoms of artichokes. Parkinson, in whose time it was introduced, calls it *Battatas de Canada*. Coles describes them, forty years afterwards, as the Potatoes of Canada. In Martyn's edition of Miller's "Gardeners' Dictionary" we are informed that they were called so because the French brought them "first out of Canada, to these parts; not that they are natives of that country, but had been introduced there from Brazil." A writer in the "Penny Cyclopædia," but upon what authority he does not mention, says this plant was introduced into Europe at the Farnese garden at Rome, from whence it was originally distributed. They were first planted in England in 1617, and so rapidly did their cultivation proceed that before 1629 they were so common in London "that even the most vulgar began to despise them." Parkinson remarks that in his time "they were baked in pies, with marrow, dates, ginger, raisins, sack, &c.; but the too frequent use, especially being so plentiful and cheap, hath rather bred a loathing than a liking for them." We notice this plant thus largely because the advent of its restoration to cultivation has commenced, and also to show that they may yet be produced abundantly, which their long-neglected state induces some to doubt. "The potatoes of Canada," says Coles, "called by ignorant people Jerusalem artichokes, were of great account when they were first received amongst us, but, by reason of their great increase, they are become common, and consequently despicable,

especially by those who think nothing good unless it be dear; but if any one please to put them into boiling water, they will quickly become tender, so that being peeled, sliced, and stewed with butter and a little wine, they will be as pleasant as the bottom of an artichoke."

The whole genus, except *S. tuberosus*, flowers most profusely, but, in consequence of its seldom producing flowers, few varieties have been produced. This is to be regretted, because if so, improved varieties might be expected, as has occurred in the case of the potato. Some varieties are said to have been produced in France, where it is much more extensively grown than with us, but of their merits little has hitherto transpired. The improvement wished for would be, increase in the size and number of the tubers, and a dwarfier habit in its growth. From the experiments made by Messrs Payen, Poincot, and Terrey, and published in the "Jour. de Pharm.," vol. xvi. p. 434, it appears that 100 parts of the tuber contain 23.96 parts of nutritious substance, or twice as much as is obtained from the potato, and something more than the cerealia contains. The tubers on which these experiments were made were grown on a sandy soil of moderate goodness, which had been manured with ammoniophosphate of magnesia. A state of flowering might be induced by removing the tubers as soon as formed, so as to throw the strength which would otherwise be consumed by them into the stem, on the principle pointed out by Mr Knight in regard to causing early potatoes to produce flowers. "I took," he says, "several methods of placing the plants to grow in such a situation as enabled me readily to prevent the formation of tuberous roots, but the following appearing the best, the others need not be referred to. Having fixed strong stakes in the ground, I raised the mould in a heap round the bases of them, and in contact with the stakes; on their south sides I planted the potatoes from which I wished to obtain seeds. When the young plants were about 4 inches high, they were secured to the stakes with shreds and nails, and the mould was then washed away by a strong current of water from the bases of their stems, so that the fibrous roots only of the plants entered into the soil. The fibrous roots of this plant are perfectly distinct organs from the runners which give existence, and subsequently convey nutriment, to the tuberous roots; and as the runners spring only from the stems of the plants, which are, in the mode of culture I have described, placed wholly out of the soil, the formation of tuberous roots is easily prevented: and whenever this is done, numerous blossoms will soon appear, and almost every blossom will afford fruit and seed." From this Mr Knight concluded "that the same fluid or sap gives existence alike to the tuber and the blossom and seeds, and that whenever a plant of the potato affords either seeds or blossoms, a diminution of the crop of tubers, or an increased expenditure of the riches of the soil, must necessarily take place." By these means he succeeded in producing varieties of sufficiently luxuriant growth and large produce for

general culture, which never produced blossoms.—*Horticultural Society's Transactions*, vol. i. p. 188.

If similar means were adopted in the case of the Jerusalem artichoke, there is little doubt that improved varieties would be produced; and in their case the want of blossoms may arise as much from their disposition to form tubers in an early stage of their growth, as from (as is generally supposed) a deficiency of climate.

*Use.*—The tubers may be used in every way like the potato, and, being more nourishing and less flatulent, may be eaten by people in delicate health, when debarred from the use of most other vegetables. They make one of our best white soups, "Soup de la Palestine." They are often planted in game-preserves as food for pheasants, and hares and rabbits are remarkably fond of them.

*Propagation.*—The small tubers are saved for planting whole, or the larger ones may be cut into one or two pieces the same as potatoes, only care must be taken that one eye or bud at least be retained in each set.

*Planting.*—Like potatoes, they may be planted the same day the crop is taken up in autumn, or at any other time when the ground is dry till the beginning of March.

They are planted in every respect as recommended for potatoes, only they require a greater distance between the rows on account of their great height, which often extends to from 6 to 10 feet, and also the large size of their foliage. The best method is to plant them in single lines at a considerable distance apart, for the same reason and in the same way as recommended for the late-growing kinds of pease.

The usual mode of setting the tubers is to dibble them in, as is often done in the case of the potato—and in both cases improperly, because, the sets not being all of the same size, the smallest ones drop to the bottom, while the larger ones are often left suspended midway down, coming in contact with the sides of the hole, thus leaving them at unequal depths, and the latter in the worst possible position for enabling the radicles of the young roots to reach the soil. It is much better, in planting all tubers, and even very large seeds, to open drills with the hoe or spade, and to place the tubers in the bottom. Another good way is to place them in the bottom of the trench, either above or below the manure (when such is applied), as the process of digging goes on. This latter way

is much the best when the land is wet or the soil strong, as treading upon it in either case, after being newly trenched or dug, would be injurious. When the sets are drilled in, they should be covered by the hoe or rake, and the soil placed over them left as loose as possible; and in either way the tubers should be kept as near as possible to 6 inches under the surface.

A piece of ground richly manured, and in an open situation, should be prepared, by being either trenched or deeply dug. The total neglect of these two conditions has long been the ruin of this esculent root, which, in general, is pushed away into some out-of-the-way corner, as if it were "branded with a mark of disgrace, and unworthy of being seen amongst the plants of the garden." In such situation it is allowed to remain for years neglected, and only visited when its tubers are sought for, which, in consequence, are small, and scarcely fit for the purposes of the cook. The tubers should be set 3 feet apart, if set in continuous rows, row from row, and 2 feet distant in the line. They will require no other attention till the following autumn, excepting keeping the ground clear of weeds. In regard to produce, they will yield as heavy a crop as ash-leaved kidney potatoes; and the nutriment contained in that quantity will be more than double. It has been recommended to top the stems when about 3 feet in height, in the expectation of throwing a greater amount of nourishment into the tubers: this has not, however, been found to be the result; while the shortening of the stems makes them send out numerous side branches, causing shade, of which the plant is very impatient. From experiments made in the extensive nurseries of Messrs P. Lawson and Son, it clearly appears that topping, instead of being beneficial, is really injurious. The produce of a row 60 yards in length of plants topped, yielded only 144 lb., while that of the adjoining row, of equal length, yielded 163 lb. Neither of these rows had guano or any other kind of manure applied to them. A third row had 8 oz. of Peruvian guano applied to the surface of the soil when the stems were 3 inches in height—it yielded 188 lb.; while a fourth had a like quantity of guano applied at the same time, *but*

buried 1 inch under the surface near the roots of the plants, in which case the produce was 210 lb. We have had on a poor peaty soil, manured as for potatoes, even much greater returns of crop.

Of all the substitutes recommended for the potato, no one is so likely to answer our anticipations as this. It is of as easy culture, equally hardy, affording twice as much nutriment, cooked in the same manner, and capable of being cultivated in the same soil.

*Soil and manure.*—A light, warm, sandy, loamy soil, or a peaty soil, with a sufficient amount of sand to sharpen it and keep it open, is the best for this crop. In over-rich soils it is apt to grow too much to stem, and in close shaded places it is liable to be drawn up tall and slender; in either case, with a less weight of tubers than in soils less enriched, and situations better exposed to the light and air.

*Taking the crop, and subsequent preservation.*—Taking the crop should be delayed so long as there is growth in the plants; for as long as vegetation goes on, the tubers will be increasing in size. Where the ground is not required, the stem may be cut over a foot from the ground, and the tubers left in the ground till wanted, as they are apt to turn blackish in cooking when exposed to the light. If the

ground is required, the tubers may be dug up and stored by as recommended for potatoes, separating the smaller from the larger, and replanting the former in ground cleared of some of the brassicaceous or leguminous crops, but not in ground which has borne a crop of tuberous-rooted plants. Great care should be taken, in lifting the crop, that every tuber may be extracted; and the roots should also be cleared off the ground, as every tuber, however small, will grow, and prove troublesome to the succeeding crop. The best way to lift them is to introduce a three-pronged

Fig. 95.

THREE-PRONGED FORK.

ground as to reach below the tubers; to lift the mass as entire as possible; and to place it on the surface, when the tubers

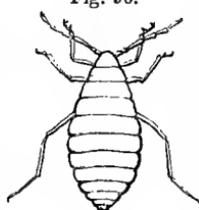

may readily be picked out. A few for immediate use may be buried in sand in the root-cellar, for it is a slovenly and time-wasting process to have to go to the plantation for a few roots as they may be required; and as the taking of them, in this way, is generally done in haste, there is a greater risk of leaving some of them behind.

*List of approved sorts.*—Generally it is considered that there is only one variety; this opinion, however, is incorrect, and arises out of the neglected state this excellent tuber is allowed to remain in. If the crop be carefully examined, as it should be, it will be found that there are some varieties better than others, both in size and form of tuber, and height of stem. Those, therefore, which show evidence of improvement in these respects should be saved for planting; and, in the absence of varieties being originated from seed, this is the only means at present in our power of improving their quality.

In an excellent work recently published by Messrs P. Lawson & Son, the eminent nurserymen in Edinburgh, entitled "Synopsis of the Vegetable Productions of Scotland," we find two varieties described—the "Common Jerusalem Artichoke," and the "Yellow Jerusalem Artichoke"—of which latter it is said, "The tubers of this variety are of a yellowish colour, and generally smaller and more irregularly shaped than the common sort; they are also said to be superior in quality, and of a more agreeable taste when cooked."

*Rhizobius Helianthemi* (the Jerusalem artichoke aphid, fig. 96).—Few cultivators, we sus-

Fig. 96.

JERUSALEM ARTICHOKE APHIS.

pect, have any idea that this proverbially hardy plant is no more exempt than almost all others from the attacks of aphides. Such, however, is the case; and, stranger still, instead of feeding upon the foliage, as most other aphides do, this one feeds upon the tubers, and forms one of a section of this tribe whose habitations are subterranean. The species, however, to which we now refer, confines its operations entirely to the surface of the roots of this plant, thrusting its long proboscis into the tuber, and thereby deriving sustenance. The writer of the article *Entomology* in the "Gardeners Chronicle" (1848, p. 399), thus lucidly describes it: "We have found these insects, in the middle of winter, on digging up the tubers of this plant, generally secreting themselves in the crevices formed by the juxtaposition of two or more of the tubers. Here they are to be found in small societies, consisting of one or two large individuals (females), and a few small and more slender ones (young). Of course, were they to occur in great numbers,

they would deteriorate the quality of the vegetable; but we have seldom found above two or three dozen upon some of the scattered tubers. The full-grown insect is opaque, white, with a slight buffish tinge, finely sericeous and setose; the head and first segment of the body with a slightly greyish-brown tinge, and the legs and antennæ of a light buffish brown. The antennæ are moderately long, and apparently six-jointed, the third joint being the longest; under a powerful lens, the extremity of the sixth joint exhibits some traces of articulation. The mouth is constructed in the same manner as all the Aphidæ, and other homopterous and hemipterous insects. The four anterior legs offer nothing peculiar; their tarsi are two-jointed, but the two hind legs are inserted quite at the sides of the body; they are long, with a long tarsus, composed of a single joint, armed at its extremity with two hooks; the peculiar lateral insertion of this pair of legs enables the insect to throw them upwards, backwards, and forwards, in the same manner as a dytiscus throws its hind legs about. We observed that they used these hind legs as feelers; the abdomen is destitute of the saccharine tube of the winged species of the family." The habits of this insect naturally point out to us a remedy against its attacks, by taking the tubers up, and washing them in lime or salt water, and afterwards storing them by for use; and it is probable that the small ones used for seed, if served in the same way, and immediately planted in a different part of the garden from where they grew, would be secured against their attacks.

*General remarks.*—The European names are—Topinambour and Poire de Terre in French; Erde Apfel in German; Aardpeeren in Dutch; Girasole in Italian; Girasol in Spanish.

## § 5.—RED BEET.

*Natural History.*—Red Beet (*Beta vulgaris* L., var. *rubra*) belongs to the natural order Chenopodæ, and to the class Pentandria and order Digynia in the Linnæan arrangement. The generic name is derived from *Betta*, red, in Celtic, in allusion to the colour of its roots; others ascribe it to the second letter in the Greek alphabet, *beta*, from the fancied resemblance to it of the seed-vessel. The cultivated beets are natives of the south of Europe. The red beet was introduced into this country in 1546. One species, *Beta maritima*, or sea-beet, is a native of our southern sea-shores; its roots are not valued, but its leaves make a good substitute for spinach, and are used as such. It would appear from Pliny that Sicily is the native country of our cultivated beets, as, in his day, the Greeks were in possession of both a black and white sort: the latter they called Sicilian beet. Few esculent plants were held in greater estimation than this by the epicures of ancient Rome. Several varieties have been long, and are still, cultivated on the Continent, for being manufactured into sugar.

*Use.*—The roots are the only parts used, and are boiled and stewed, and eaten cold, with vine-

gar and oil, in slices. They enter into mixed salads, and are much used for garnishing; and for all these purposes the deeper coloured they are the more they are appreciated. Some, however, it ought to be noticed, prefer them of a bright-red colour, but all must be of fine quality in fibre, solid, and of uniform colour. The roots are also eaten cut into thin slices, and baked in an oven; dried and ground, they are sometimes mixed with coffee, and are much employed as a pickle. The juice of the roots is sometimes used by young females in the Highlands as an economical *rouge*. Mixed with dough, it makes a wholesome bread, but for this purpose the white or yellow-rooted sorts are preferred. The roots of all the sorts are better baked than boiled.

*Propagation.*—All the varieties are produced from seed, which vegetates more rapidly if steeped, six or eight hours previous to sowing, in tepid water: when sown in dry soil, without this precaution, they are tardy in coming up—a circumstance noticed by Pliny, but rather overstretched by that historian. He says, the seed has "a strange and wonderful quality, for it will not all come up in one year, but some in the first, others in the second, and the rest in the third year." This slowness in vegetating should be taken into consideration, and the seed committed to the ground as recommended for carrots, else the weeds are apt to get ahead of the crop, and so render hoeing more tedious: one ounce of seed will sow a drill 150 feet in length.

*Sowing and planting.*—Three separate sowings should be made—namely, the first in the last week of March, the second in the second week of April, and the third at the end of that month. If the seed is new, and the spring cold, plants for an earlier sowing would be apt to run to seed, instead of forming bulbs; yet, in families of distinction, where beet is required all the year, a small sowing should be made in a warm border, about the end of February, or, with much greater success, on the 1st of March, upon a very slight hot-bed. The London growers "are very particular about the time of sowing it, for one week too soon sown spoils it. It is generally put in about the first week in May; but even with the same seed, and same soil, it makes a great difference if it is transplanted, because, in removing the seedlings, all forked ones are thrown away. In this operation great care must be taken that the points of the roots are not broken off."—CUTHILL, p. 26.

Beet sown too early is liable to be killed by the late spring-frosts.

The superior varieties of beet for salad purposes do not grow very large nor long ; yet, from their fusiform shape, it is necessary that the ground should be deeply trenched or dug, and finely pulverised, that the roots may meet with no obstruction in their descent, to induce their becoming forked or misshapen ; and, for the same reason, recent manure should not be applied, but ground employed which is in good condition, such as that from which celery has been removed. Although all the beets transplant well, if done while the plants are small, still it is better to sow in drills than broadcast—either to leave the crop in that way, or to transplant it entirely. These drills should be 18 inches apart, and 2 inches deep. Some pierce holes, 2 inches deep, with a blunt dibble, at the distances at which the plants should ultimately stand in the rows, and drop three or four seeds in each, thinning out the plants after they come up, so as to leave only one in each place. There can be no objection to this mode, more than that of sowing in the opened drills, provided care is taken to place the seeds at a proper and uniform depth. In strong retentive soils beet seldom grows so clean, nor will it vegetate so freely, as in light sandy soils. To obviate this defect, and secure well-formed roots, some drive a dibble 4 inches in diameter into the ground, a foot or 15 inches deep, at the distance of 9 or 10 inches apart, and fill these holes with sand, in which a little salt and guano have been mixed ; in these the seeds are dropped, and thinned out as above. The roots, by this means, have less inducement to fork or send out side fibres, and in general are produced of good form and size. When blanks occur in the lines, at the period of thinning, the superfluous ones may be taken carefully up with the small planting-fork, fig. 55, as it is immaterial whether much soil is attached to the roots or not ; and if planted in the blank spaces, on a moist day, they will succeed perfectly ;—only care must be taken that the roots are not doubled up during the operation, but extended to their whole length, and the soil gently, and not too tightly, placed around them.

*Subsequent cultivation.*—Thinning the crop to the distances stated above, and

keeping the ground clear of weeds, constitute all that is required till the roots are fit for taking up.

*Soil and manure.*—The soil in which the beet thrives best is that of a deep, light, sandy nature, rather dry than moist ; and the best manure, if such be required, is guano, soot, and salt, in equal proportions, and applied when the seed is sown ;—or, should the crop look weakly after it is 6 or 8 inches high, applied to the roots in a liquid state. Pigeon dung incorporated with the soil during the previous winter has been found beneficial ; and spirits of tar, applied at the same time, has secured the roots from the attacks of wire-worm. Much of the sweetness and tenderness of the roots depends on the soil : on poor light soils, as also on heavy ones, the very best varieties will taste earthy and unpleasant. Salt is a beneficial application to this crop, as well as to the green and silver beets—one reason for which undoubtedly is, the beet being a native of the sea-shore.

*Taking the crop, and subsequent preservation.*—By the beginning of September in England, or the latter end of that month in Scotland, the roots will be of a good size for use, and by the end of October in both they may be taken out of the ground altogether. They are sometimes destroyed by frost, more especially in the north ; but leaving them in the ground destroys their colour, for which reason it is better to take them up and place them amongst sand, along with other roots, in the root-cellar, or to store them after the manner of potatoes (*vide* p. 218). The London market-gardeners winter their “beet in large sheds stored in moderately damp mould, and banked up with straw. It is a mistake to pack it up in dry sand or earth for the winter ; and the same may be said in regard to carrots, parsnips, salsify, scorzonera, and similar roots.”—CUTHILL in *Market-gardening around London*, p. 26. The object here is, that the moist soil may not draw the natural sap out of the roots so readily as dry sand or soil would do, and hence their tenderness ; and possibly, in the case of the beet, the colour also may be preserved. In taking up the roots, the greatest care must be exercised that they are neither cut, broken, wounded on the skin, nor any of their fibres removed ; and when the small-leaved varie-

ties are grown, few if any of the leaves should be cut off. A dry day should be chosen, and when the roots have been exposed for a few hours, to dry the soil that may adhere to them, they should be packed by as noticed above. Some prefer packing the roots, for preservation during winter, in sifted coal-ashes, assigning as a reason that ashes are less likely to encourage decay; and others recommend placing them on shelves elevated a little above the floor in dampish cellars, believing that the air passing around them tends to their preservation. Both plans may be good in very damp cellars, but otherwise the roots would be liable to become shrivelled and dried up. The leaves should not be cut off closer to the crown of the root than 6 or 8 inches. The roots will keep till the July following.

*List of approved sorts and their qualities.*—*Whyte's black.*—Judging from its appearance in a growing state, it would be by most pronounced a coarse sort, on account of the largeness and want of red colour in the leaves. It is, however, the darkest beet grown, but should not be sown before May.

*Castlenaudari.*—A good variety, brought into notice some years ago by the London Horticultural Society. It is much used in France, and prized on account of its flavour, which resembles that of the kernel of a nut. It is the *Bette-rave rouge de Castlenaudri* of the "Bon Jardinier."

*Glen Dwarf-red.*—A very excellent crimson variety grown by Mr Handisyde of the Glen nurseries, Fisherrow; roots scarcely 9 inches in length, of uniform shape, not disposed to fork, with small thin dark-coloured leaves, scarcely 7 inches in length.

*Cuttel's dwarf-red and Atkins' crimson.*—Very similar to the last, all the three growing a good deal above ground.

*Small deep-red.*—We have grown this and the following for several years from the stock of Messrs P. Lawson and Son, who describe it in "Vegetable Products of Scotland," p. 24, thus: "Leaves rather small and spreading, of a very deep red colour; roots growing more above ground; smaller and more bluntly tapered than those of the common 'red beet,' both in skin and flesh of a much deeper blood-red colour. Known also as superb deep blood-red."

*New blood-red or mulberry.*—"This seems a sub-variety of the small deep-red, from which it differs chiefly in being of a much darker or almost blackish mulberry colour."

*Barrot's new crimson.*—This very excellent variety is less liable to fork than the *Castlenaudari*; colour very dark crimson, leaf-stalks tinged with yellow. Considered by Mr Thomson the best beet grown.

*Insects and diseases.*—The beet is not very

liable to either, if in proper soil and under good cultivation.

*General remarks.*—The European names are *Bette-rave* in French; *Barba-Biettola* in Italian; *Biet-wortel*, or *Karott*, in Dutch; *Rothe Rube* in German; and *Betarraga* in Spanish. In sowing seed, select the best formed roots, and try the colour by making a slight incision, which afterwards dry up with a little caustic lime. Both form and colour constitute their merits. Transplant them, and treat them as recommended for carrots and parsnips. Only in cold situations plant them in a warm sheltered place, against a south wall if there is room, or support them with stakes as the flower-stems extend, to prevent their being broken by the wind. One plant will produce seed enough for a small garden. No two varieties should be thrown together; and as the seed will retain its vegetative properties for nine or ten years, it is better to save one sort only annually.

## § 6.—SALSIFY, SKIRRET, ETC.

*Salsify* (*Tragopogon porrifolius* L. —leek-leaved salsify) belongs to the natural order Compositæ, tribe Scorzonereæ, and to the class Syngenesia Æqualis in the Linnæan arrangement. The generic name is derived from *Tragos*, goat, and *pogon*, beard, from the bearded appearance of the seeds—vulgarly goat's-beard; the specific name from *Porrium*, the leek, on account of the resemblance of the leaves to those of the leek. Indigenous to England, but not very common. The roots, which are the only parts eaten, are long, white, and fleshy, tapering like the parsnip, but never attaining the same diameter. *Tragopogon pratensis* was cultivated in gardens in the time of Parkinson; but that species has been superseded by our present subject. It has been hitherto confined to gardens of the first order, but would be worth the attention of amateurs, as affording an additional dish of vegetable diet.

The roots are used simply boiled, like carrots and parsnips; the flavour is mild and sweetish. Dressed like asparagus, there is some resemblance in taste; and the flower-stalks, if cut in spring on the second year before they become hard, and dressed like asparagus, make an excellent dish.

It is propagated by seed sown in drills annually in March, April, and towards the latter end of May for succession. The drills should be 18 inches apart, and 2 inches deep. When the plants come up, thin to 6 inches in the lines, and keep them clear of weeds. In August and September, and thence through the winter, the roots will be fit for use; and in November, take up those remaining, and store them by for winter use in the same manner as parsnips. They are quite hardy, and may remain all winter in the ground, if it is not required for re-cropping or improving. One ounce of seed will sow a drill 40 feet in length. To increase the size of the roots, water with liquid manure during hot dry weather. The seed keeps good for four years.

Save seed in the same manner as with carrots; one or two plants will afford a supply for a small garden. It is not subject to the attacks of insects, although hares and rabbits are exceedingly fond of it. It is, however, almost invariably attacked by *Erysiphe cichoracearum*, Link, a small parasitic fungus, one of the mildews; but it has not the effect of injuring the growth of the plant much, as it is late in summer when it makes its appearance, in the form of numerous white blotches. This vegetable is much cultivated in France. The European names are—Salsifis in French; Sassifica in Italian; Bocksbart in German; Barba cabruna in Spanish; and Boksbaard in Dutch.

The *Skirret* (*Sium sisarum* L.) belongs to the natural order Umbelliferae, sub-order Orthospermæ, and tribe Ammineæ, and to the class Pentandria and order Digynia in the Linnæan arrangement. The generic name is derived from *Siu*, water, in Celtic. The specific name is from *Dgizer*, the Arabic name, which signifies carrot. A native of China. Introduced before 1548.

*Use*.—The roots, which are composed of small fleshy tubers, joined together at the head or crown, are the parts eaten. When boiled, they are eaten with butter, and are sweet and very agreeable. They are much used in French cookery, and more cultivated on the Continent than with us, although there are few gardens of importance without them.

Their cultivation is similar to that of salsify, only they are propagated both by seeds and by offsets taken from the old roots. The better way, however, is by seed.

The European names are, Chervis in French; Sisaro in Italian; Zuckerwortzel in German; Suckerwortel in Dutch; and Chirira-tordesca in Spanish. In the north of Scotland, according to Loudon, it is cultivated under the name of Crummock.

*Scorzonera* (*Scorzonera hispanica* L., Spanish *Scorzonera*) belongs to the natural order Compositæ, sub-order Cichoracææ, and tribe Scorzonereæ, and to the class Syngenesia and order Æqualis in the Linnæan arrangement. The generic name is derived from *Scurzon*, the Catalan name of the viper. The plants are esteemed in Spain as a certain remedy for the bite of a viper; but it is believed that the slender tortuous form of the roots has given rise to this belief, rather than any quality inherent in the plant; for it is a rule to which there are very few exceptions, that all plants used as food by man possess very inactive qualities. If their action was powerful, they would be unfit for food.—*Encyc. of Plants*, p. 668. It is a native of Spain, and was introduced to Britain before 1576.

The roots, which are long, black, and tapering, about  $\frac{3}{4}$  of an inch in diameter at top, are the parts used. They are boiled or stewed after the manner of parsnips; the outer rind is scraped off, and the roots placed to steep in cold water for several hours, to extract a part of their bitter flavour. It is also variously used in French

and Italian cookery. It is found in all our best gardens, but, like salsify and skirret, occupies about one-fifth the space that parsnips do.

It is propagated by seeds; and its cultivation, in all respects, is similar to that of salsify and skirret, only requiring about 4 or 5 inches more space between the rows, and 3 inches more between the plants in the lines. An ounce of seed will sow a drill 40 feet in length. Few insects trouble it; but, like the salsify and skirret, the *Erysiphe cichoracearum*, or mildew fungus, sometimes attacks it. Its European names are—Scorzonere, or Salsafis d'Espagne, in French; Scorza-zera in Italian; Skorzonere in German; Escorzanera in Spanish; and Skorzoneere in Dutch.

*Hamburg parsley* (*Apium petroselinum* L., var. *Tuberosum*, "Bon Jardinier") belongs to the natural order Umbelliferae, sub-order Orthospermæ, and tribe Ammineæ, and to the class Pentandria and order Digynia in the Linnæan arrangement. The generic name is derived from *Apon*, water, Celtic, from its place of growth. This refers more especially to *Apium graveolens*, the common celery. The Hamburg parsley is a variety of the common sort, *Apium petroselinum*, having large fleshy roots, and for these it is cultivated.

The roots as well as the leaves communicate an agreeable flavour to soups and stews. It is much grown in Germany, and was formerly so in England, and often cooked like the parsnip or the yellow turnip.

It is propagated by seed, which is sown at the same time as parsnips, and the routine of culture differs not from that of that plant.

## § 7.—THE PARSNIP.

*Natural history*.—The parsnip (*Pastinacea sativa* Tourn.) belongs to the natural order Umbelliferae, sub-order Orthospermæ, tribe Peucedaneæ, and to the class Pentandria and order Digynia in the Linnæan arrangement. The name is derived from *Pastus*, nourishment; or, according to others, from *Pastinum*, a dibber or dibble, the root resembling that implement in form. Indigenous to Britain; found generally in calcareous soils and in waste places. Like the carrot, it is difficult to say whether it is to cultivation or importation that we are indebted for this root in its present state—most probably to the latter—and that it may have been brought from Germany or Italy. Phillips asserts (but of this we have doubts) that if the wild parsnip is grown for two or three years successively in rich soil, it will assume all the characters of the cultivated sort. It appears to have been early reclaimed and cultivated on the banks of the Rhine, for Pliny says they were brought from thence to the Roman emperors' tables. Gerard speaks of a broad-leaved and narrow-leaved variety being grown in gardens in his time.

*Use*.—In former times the parsnip was more generally used as an article of food than at present, and was with us then, as in Roman Catholic

countries at present, used with salt fish during the season of Lent. It is a good substitute for the potato, yielding a large return of very nourishing food, and is often, by country people, eaten when mashed up with that root. Parsnips contain a very considerable portion of sugar, and from this cause they yield a very excellent spirit by distillation. In the north of Ireland the cottagers obtain a sort of beer by mashing the roots and boiling them with hops, and then fermenting the liquor. Wine closely approaching in quality the Malmsey of Madeira is made from the roots; and marmalade made with parsnips and a small quantity of sugar is thought to excite appetite, and to be a very proper food for convalescents. Bread has also been made from the roots; and in Holland they are much used in soup. The present demand for them, however, is to be eaten with fish or other salt meats.

*Propagation.*—Always by seed, which is flat, thin, and light. Half an ounce of seed will sow a bed of 100 square feet, if sown broadcast, and the plants afterwards thinned to 8 or 9 inches distance. The seed will vegetate sooner if steeped in water, as recommended for carrot-seed.

*Sowing and planting.*—The seed should be sown as early in spring as the ground is in a proper state of dryness to receive it. As the roots extend to a considerable depth, the ground should be trenched at least 2 feet deep. The drill-system is the most proper to follow: the drills should be from 15 to 18 inches apart, and 2 inches deep; and when the plants attain the height of 3 or 4 inches, they should be thinned to 6 or 8 inches in the line. Where they come up too thick, they should at that stage be thinned; and as they transplant readily at that age, any blanks in the rows may be made up, or the plantation extended by additional rows.

*Subsequent cultivation.*—Keep the ground clear of weeds by hoeing, which should be shallow, for reasons given in article CARROT.

*Soil and manure.*—A light pervious deep soil is the best; and if in moderate condition, by the manuring of the previous crop, it will be better than applying manure at sowing. Should it be necessary to do so, let the manure be in the most decomposed state possible, or, if otherwise, lay it in the bottom of the trenches as the trenching proceeds. It will grow in a stronger soil than the carrot, and succeeds well in sand or in peat, if sufficiently manured. Soap-boilers' ashes have been advantageously employed as a manure for

the parsnip, carrot, and potato; and where laid on to the extent of a pound-weight per square yard, have had good effect in resisting the attacks of insects at the roots.

*Taking up the crop, and subsequent preservation.*—By the end of September the most forward roots will be fit for use; but the general lifting should not take place till the leaves are killed by the frost. It is a much hardier plant than the carrot; and therefore, if the ground is not required, and the roots are free from disease, they may be left in the ground till spring with safety: otherwise they should be dug up, and their tops taken off as recommended for carrots, and either packed in sand in the root-cellar, or pitted as recommended for potatoes. In general it is best to take up all such crops, so that the ground they occupy may be manured and trenched during winter.

*Approved sorts and their qualities.*—*Long Jersey.*—An improved variety of the common sort, being much larger and thicker towards the top. This is the variety cultivated in the Channel Islands, where the cultivation of this plant has been long successfully carried on. The crown is somewhat concave or hollow—hence it is often known as the hollow-crowned, Guernsey, and hollow-headed. It is the Panais Lisbonnais of Guernsey. Roots 18 inches long, and often from 4 to 5 inches in diameter at the top. The best variety for cultivation.

*Common long-rooted.*—Scarcely so large as the last; crown or top slightly convex. This is the Panais longue of the French, the Panais coquine of Guernsey, Jersey parsnip, and Guernsey parsnip.

*Turnip-rooted.*—This variety is much smaller than either of the last, of good quality; and as its roots are short and somewhat turnip-shaped, it is adapted to thin soils. It is the Panais rond and Panais royal of the French. Root formed almost on the surface of the ground, and attaining the size of from 4 to 6 inches in diameter.

*Early short-horn.*—A recently introduced sort, of delicate flavour and appearance on the table. A smaller and shorter sort, if of improved flavour, would no doubt be valuable, as our present sorts are too large to appear whole.

The late Dr Neill, in "Edinburgh Encyclopædia," mentions the *Le Batard ou de Siam yellow*, apparently intermediate between the turnip-rooted and long-rooted varieties, and of more richness in flavour and tenderness of flesh than any of the others. It does not appear to be in our seed-lists, although mentioned by Noisette in "Manuel Complet du Jardinier." The introduction of this variety would, for garden purposes, be important.

*Insects and diseases.*—"The parsnip is subjected to the attacks of a few insects. The maggot of the parsnip-miner (*Tephritis onopordonis*, fig. 53)

are hatched from May to July, and feed upon the parenchyma or pulp of the leaf, causing large blisters upon them; and when two or three larvæ are feeding on the same leaf, the blisters unite and form large discoloured patches; but otherwise the mischief is not serious. The caterpillars of the flat-bodied moth (*Depressaria pastinacella*) infest the parsnips left for seed, and often much injure and diminish the yield. They prefer the parsnip to the carrot seed; and on this account the growers of carrot-seed sow some parsnips beside them, by which to lure the insect from the carrot crop. These caterpillars are greyish blue, with the head, thorax, and pectoral feet black; upon each of the segments are six distinct little black dots, producing single minute hairs; the sides and the belly are yellow, and the abdominal feet are dotted with black. They live in July upon the flowers and young seeds of the parsnip. There seems to be no better mode of ridding parsnip crops of these caterpillar pests than hand-picking, and shaking the umbels of the flowers over a vessel for them to fall into. The flower of the parsnip is not

nearly so liable to be affected by insects, damp, or mildew as that of the carrot, on which account the crop of seed is a surer one, though it should be borne in mind that it will not retain its vitality beyond one year."—*Jour. of the English Agr. Soc.*, vol. i. p. 419, as quoted in "Book of the Farm," vol. ii. p. 100. Besides these, the *Depressaria applana*, *D. daucella* (the carrot-blossom moth), in the caterpillar state, make great havoc on the seed-crop of parsnips also.

*General remarks.*—The European names are—Panais in French; Pastinaca in Italian; Charibaria in Spanish; Pastinake in German; and Pinksternakel in Dutch. Seed is saved in the manner recommended for carrots. The quantity produced from one plant will be sufficient for a small garden; and, according to Mr Stephens, "from 1½ lb. to 4 lb. of seed, being very light, may be expected from a square rood of 16½ feet, dependent on the nature of the season, and escape from the attacks of insects. Birds do not injure it, though, if the seed is not gathered from the umbels as they ripen, they are very apt to be blown off by the wind."

## CHAPTER VIII.

### OLERACEOUS PLANTS, OR POT-HERBS,

COMPRISING SUCH AS ARE USED FOR GARNISHING AND SEASONING.

THE plants which constitute this chapter, being chiefly aromatic, should be accommodated with a light poor soil, and be cultivated by themselves, on whatever scale the garden may be; and if we except the common parsley, which requires to occupy a considerable space, a bed or two at most of the others will be found sufficient. The situation chosen for them should be some snug and convenient spot, sheltered and warm, as the majority of these herbs delight in a warm sunny spot; convenient, because some or other of them are in daily use, and if scattered over the garden, as is too often the case, much time is lost in collecting them. To prevent mistakes, every variety should be legibly named at the end of the bed next to the walk; and the smaller the garden is, the more necessity there is for this being attended to.

#### § 1.—PARSLEY.

*Natural history.*—Parsley (*Apium petroselinum* L.) belongs to the natural order Umbelliferae, to the sub-order Orthospermæ, and tribe Ammineæ, and to the class Pentandria Digynia in the Linnæan arrangement. The generic name is derived from *Apon*, water, Celtic, from the place where the plant grows; and the specific name from *petre*, a stone, and *selinum*—stone celinum. It is a native of Sardinia, introduced about 1548. Gerard spells it *parsele*, *parsely*, and *parsley*; and says it “is delightful to the taste and agreeable to the stomach.” Phillips asserts that “parsley easily resisteth the cold and the heat, if it be sown on a rich damp soil, or near a spring.” This is a very different condition, as to situation, to what it enjoys in cultivation; and hence cultivators in general sow it in dry exposed places, to avoid its damping or rotting off during winter, which it is very apt to do in strong damp soils, be they ever so rich; and in much elevated situations it is with great difficulty preserved during winter and spring. That it would succeed better if planted near a spring is possible, as the water rising from a great depth is higher in temperature than the surrounding atmosphere, and hence springs seldom freeze. Few, however,

have such springs at command, and so completely protected as to exclude hares, which are exceedingly fond of this plant. Indeed, it has been sown often in preserves, where it has been wished to encourage these destructive creatures. The seed of the common parsley has the property of remaining long in the ground after sowing before it vegetates—from forty to fifty days. Some fatal mistakes have occurred by people gathering *Æthusa cynapium* (fool’s parsley), a poisonous plant often found in old gardens as a weed, and so similar to parsley as to be readily mistaken for it; and instances are recorded where the leaves of *Conium maculatum* (hemlock) have been gathered for it in the same way. To avoid such, it would be well if amateurs, and those not sufficiently acquainted with these plants, were to cultivate the curled parsley only, which could not be mistaken for either. The plain-leaved sort, however, is hardier, and withstands the winter cold better, and therefore is often sown where the finer curled varieties would not survive.

*Use.*—Parsley is in great demand throughout the whole year for a variety of culinary purposes, and is the common garnish to all cold meats, and enters into many sauces, soups, broths, &c. It should always be brought to table when any dish is introduced that is strongly seasoned with onions, as it takes off the smell and prevents the after-taste of that strong root. Forenoon tipplers chew a leaf of parsley to prevent their breath from bearing witness against them. The leaves are gathered when quite dry, and hung up in small bundles, in an apartment heated to from 60° to 70°, to dry. In a day or two they may be pounded or rubbed down to a powdery state, and bottled for winter use. Hung up to the roof of a kitchen, or placed in a Dutch oven in the evening at a moderate distance from the fire, they will be in a fit state by morning for pounding. It retains its flavour long when dried, if kept excluded from air. In this state it is excellent for seasoning omelets and all similar dishes.

*Propagation.*—It is propagated by sowing the seed only. An ounce of seed will sow a drill 150 feet in length.

*Sowing.*—Sow early in February, if the ground is dry; if not, from thence till the end of March. Another sowing should be made in May, and another in July, for young plants to stand over winter. To insure the finest curled varieties, the plants should be transplanted once at least; and if oftener, it is said, the more certain will be the result. Sow, therefore, either thinly broadcast or in drills, covering, in either case, to the depth of three-quarters of an inch. When the plants are fit to handle, take them carefully up, preserving their long tap-roots quite entire, and transplant them in lines 18 inches asunder; but where the ground is rich, and the variety extra curled, 2 feet will be a more proper distance. Set the plants carefully with the dibble, at first 3 inches apart; and after they have commenced growing for a week or so, thin out to 6 inches, making new lines with the thinnings; and in three weeks afterwards, finally thin to 12 inches, plant from plant, in all the rows. By this means, and in a highly-manured deeply-trenched soil, we have grown the plants so large as completely to cover the surface of the ground.

Some have recommended cutting over the old plants in autumn, to secure a supply in spring. It is much better to depend on an autumnal sowing, provided the seed is sown before the end of July. In small gardens, parsley may be sown as an edging to walks or footpaths, to economise space, as well as to be readily got at when wanted for use.

*Subsequent cultivation.*—Keeping the plants clear of weeds by deeply hoeing between them, and pulling up any that prematurely run up to seed, is their summer routine. On the approach of winter, cut off a supply of leaves for drying, as already noticed; remove decaying leaves, to prevent damp; and shelter the winter standing-crop by the best means at command—of which few are better than sticking the ground around them pretty thickly with short branches of deciduous trees or broom, stuck firmly in the ground, so as not to be blown about by the wind. Cover the surface between the rows with finely-sifted coal-ashes, to counteract damp, and to keep the leaves clean. In some situations it is necessary to take up a portion of the crop, and to pot it, or

plant it in light dry soil under frames and sashes. In neither way does it do so well as protected where it has been grown. It is in such cases that drying the leaves and bottling them becomes necessary; but even in this way the dried leaves can only be used for seasoning: for garnishing they become entirely useless.

*Soil and manure.*—The first cannot be too rich, and the second should be the most potent that can be applied, particularly to summer crops; but both must be more sparingly employed in the case of crops to stand over winter.

*Taking the crop, and subsequent preservation.*—The leaves should be cut over by the foot-stalk, and not plucked over by the middle, as so often carelessly practised. Each leaf should be cut by itself, and the larger and more fully developed bottom ones taken first. When removed to the vegetable-house, they should be rinsed in clear water, and the foot-stalks of the leaves cut close off, and the leaves placed in a clean salad-basket ready for use.

*Approved sorts and their qualities.*—The original old plain-leaved is hardier than the fine curled sorts, on account of its being less succulent, and less liable to retain moisture. It is desirable to sow it in cold situations, particularly for winter and spring use; but for all other seasons and purposes,

The fine curled, or triple curled, should be preferred; and of these we have, amongst other names in seed-catalogues, the following: Myatt's, garnishing, very dwarf, and exceedingly curled.

*Engelfield extra curled.*—Very large and finely curled.

*Reid's fine curled.*—A variety we received some years ago from Mr Reid of Rise Park, Yorkshire, which is hardy, standing the damp cold of the Holderness, as well as that in many parts of Scotland which it has reached. By carefully selecting from any of the last three varieties, and by repeated transplanting and high cultivation, the finest curled parsley may be obtained.

*Hamburg parsley* (*Apium petroselinum*, var. *tuberosum*, "Bon Jardinier") is a variety of the common parsley cultivated for its large fusiform roots, as already described. It is used for all the purposes of the common parsley; and in addition, the roots are served at table as a separate dish, like the Feltow turnip or parsnip. The leaves are much larger than those of the common plane parsley, and fully as little curled.

The *Naples parsley*, or, as it is often called, *celery parsley*, appears to be a hybrid between the Hamburg parsley and the celery. In France and Italy the foot-stalks of the leaves are much used as a substitute for celery, and its cultivation is much the same. It is only in

gardens of the highest order in Britain that it is found.

*Insects and diseases* seldom attack the parsley, unless in dry seasons, and in light ferruginous soils, where either an underground grub, or, we rather think, a disease of the canker description, destroys the roots, which causes the plant immediately to die. We have never been able to detect an insect at the roots, although the effects are exactly similar to those which affect carrots, when their roots are about as large as a quill. Saturating the ground with lime-water has arrested to some extent the disease; but whether this arises from the caustic effect, or from the mere addition of moisture, we cannot say.

*General remarks.*—The European names are—Parsil in French; Petersilie in German; Peterselie in Dutch; Petroselino in Italian; Perejil in Spanish; Petruschka in Russian; Pietruszka in Polish.

## § 2.—DILL, BORAGE, ETC.

*Dill* (*Anethum graveolens* L.) belongs to the natural order Umbellifera, sub-order Orthospermæ and tribe Peucedanæ, and to the class Pentandria and order Digynia in the Linnæan arrangement. A native of Spain, and introduced to Britain in 1570. The generic name is derived from *Ano*, upward, *Theo*, to run, on account of its quick growth. Others derive it from a Greek word signifying to burn, the plant being very heating.

A hardy biennial plant seldom used, and then only for the leaves, which communicate a slight degree of its powerful aromatic flavour to pickles, and also occasionally in soups and sauces. A dozen and a half good plants will be sufficient for a large family's use. It is little more than an annual with us, therefore requires to be sown annually, either in March or April, or as soon as its seeds ripen in autumn, and in favourable places will stand over the winter.

Like all warm and high-scented plants it requires a light poor soil, because such a soil is found most favourable for the preservation of their aromatic properties, such plants being only found naturally growing on such soils. It should be grown in drills 1 foot apart, and the plants thinned out to a like distance. Leave a plant or two to run up to seed, which ripens in autumn; and if grown, as all such plants should be, in a compartment by themselves, called the olitory or herb-garden, it will shed its seeds and come up abundantly in spring; which course may be followed for three or four successive years, at the end of which the situation should be changed, and this culture begun *de novo*. The European names are—Anith in French; Aneto in Italian; and Dill in German and Dutch.

*Borage* (*Borago officinalis* L.) belongs to the natural order Boraginæ, and to the class Pentandria Monogynia in the Linnæan arrangement. The generic name is taken from *Cor*, heart; *Ago*, to affect, on account of its cordial qualities. In-

digenuous to England, in waste places amongst rubbish. Pliny says that wine with this infused in it cheers the spirits; and hence the leaves are used, but more properly the flowers, as forming an ingredient in cool tankards. The Greeks called it Euphrosynon, for, when put into a cup of wine, it made those who drank it merry. It has been in use for these purposes since the days of Parkinson. Coles and M. Valmont Bomare say the flowers have no virtue when dry, and recommend using the roots during winter, which are said to possess the same properties. In Queen Elizabeth's time, both the leaves and flowers were eaten in salads. At present it is cultivated for cool tankards, and the young shoots and leaves for mixing in salads. The leaves contain so great an amount of nitre, that when dry they burn like match-paper. It is also used by some as a substitute for spinach.

*Culture.*—The seeds are large, so that two ounces will be required for an ordinary garden, which should be sown thin, 9 inches apart seed from seed; and a spring and August sowing will be sufficient, as, if the leaves only are to be used, if the flower-stems are cut out as soon as they form, the plants will continue forming leaves for three months in succession. Self-sown plants will arise in abundance, and therefore borage may be treated in this respect as noticed for dill. The young plants transplant freely, and as they rise from self-sown seed, it is allowed to ripen. If once introduced into a garden, it will not easily be lost. Cool tankard is a beverage composed of lime-water, lemon-juice, and sugar, and is exceedingly refreshing and exhilarating during summer.

The European names are—Bourrache in French; Borrachine in Italian; and Borrage in German. The seed will keep for four years in the seed-room, and for an unknown period if deep in the ground. It makes an excellent green manure, and has been sown in spring for such, and dug in during autumn. In soils deficient in nitrous matter, the advantage of this is obvious.

*Thyme.*—Common thyme (*Thymus vulgaris* L.), a native of Spain and Italy. Introduced to Britain long prior to 1548. Of this there is a broad-leaved variety of altogether stronger growth, (*Thymus citriodorus* Pers.) lemon-scented thyme. These are the only two species cultivated; the latter is indigenous to Britain, belongs to the natural order Labiatae and tribe Satureinæ, and to the class Didynamia and order Gymnospermia in the Linnæan arrangement. The generic name is derived from *Thymos*, courage, from its smell-reviving properties. Its use was well known to the ancient Greeks and Romans, and according to Evelyn it was cultivated to a great extent in the neighbourhood of Sandwich and Deal for its seed only, which was used in preference to the leaves, and also for medicinal purposes. Both are at present used, in either a green or dry state, in soups, stews, sauces, and stuffings, and the leaves of the lemon-scented kind are used for seasoning veal instead of lemon-peel. Before the introduction of the Eastern spices, both were more used than

at present. The common sort is propagated by division of the plant, by cuttings, but best of all by sowing the seed, which should be sown early in the season, and transplanted out towards the end of summer, when the plants are about 2 inches in height. Where there is the convenience of sowing on a slight bottom-heat in February, the plants will be ready for transplanting in May, and will be fully established by the end of the season. The lemon sort is capable of increase by cuttings, and also by seed; but, being a low-creeping plant, it is usually done by division of the roots. Both should be planted a foot apart; and no soil can be too dry or almost too poor for either. Both are hardy; but for winter use the plants should be cut over when just coming into flower, tied up into small bundles, and suspended to the roof of a warm kitchen, so as to dry rapidly and retain their green colour. For the purpose of drying herbs, we have an apartment behind one of the pine-stoves, which can be heated to 60° or 70°, from the ceiling of which we suspend cords; and as the herbs of this description are cut and tied up into bunches, which should not in any case exceed an inch in diameter where the ends of the branches are secured, they are fastened to the lines, and in three or four days are sufficiently dry to be packed by in air-tight boxes, and placed one on top of the other in a dry room. When the herbs are placed in the boxes, a false lid—that is, a piece of boarding exactly the size of the inside of the box—is placed over them, and a weight placed over that, to keep them quite tight together. The proper lid is then put on, and the name of the herb written on the side of each box. In this way they are secured from damp and dust, which are both alike destructive to them. For further on preserving herbs, *vide* Section MINT. It is important that all herbs be cut when perfectly dry, and just as they are coming into flower. A judicious plan is followed by those who grow this plant for the London market—namely, by sowing the seed broadcast, and moderately thinning out the plants after they have attained the height of 2 inches. The rest are left upon the ground, and drawn up by the roots when required for use.

The European names are—Thym in French; Timo in Italian; Tomillo in Spanish; Thimian in German; Tomilho in Portuguese; Gomezeo thym in Dutch.

### § 3.—SAGE, BALM, MINT, ETC.

*Sage*.—*Salvia officinalis* L., the common sage, with its two varieties—*variegata*, the variegated, and *tenuior*, the slender; *Salvia solarea* L., common clary; *Salvia horminum* L., hormium clary; and the varieties, *violacea*, purple-topped, and *rubra*, red-topped—are all cultivated for culinary purposes. The common sage and its two varieties are, however, the most common. These are natives of the south of Europe, and appear to have been introduced about the same time (1597). The common clary is a native of

Italy, and was introduced in 1562; the hormium clary is a native of the south of Europe, introduced in 1596. The sages belong to the natural order Labiate, and to the class Diantria and order Monogynia in the Linnæan arrangement. The generic name is derived from *Salvus*, safe; according to others, from *Salvere*, to save, on account of its supposed healing qualities. It is called sage in English, from the French word *Sage*, wise, from its supposed property of strengthening the memory, and making people sage or wise.

The French make an excellent pickle of the young leaves of common sage. In Britain it is commonly used as a seasoning for strong meats, sausages, ducks, goose, &c., and was formerly much used in making sage cheese. The leaves of the narrow-leaved variety are employed in making sage tea. The Chinese use it for this purpose; and at one time the Dutch carried on a profitable trade, by procuring the leaves from the south of France, drying them to resemble tea, and disposing of it in China, where for every lb. of sage they got in exchange four of tea.

All the sages are propagated by seed and by cuttings. The plantations should be renewed every third year, as they often suffer by the cold and damp of our winters. The seed should be sown early in March upon a slight bottom-heat; and if so, the plants will be fit to plant out in May, when they should be set in lines 15 inches apart, and a foot distant in the line. Cuttings are best put in (using the young wood of the present year's growth) about the latter end of May or beginning of June, planted in a partially-shaded place, and covered with hand-glasses. The cuttings may be taken off from 4 to 5 inches in length, cutting off (not stripping) the lower leaves as far as the cutting is inserted in the ground, and leaving all the other leaves entire. They will soon, at that season, form a small callosity at their base, from which the roots proceed. At this period, air must be admitted more freely to them, and when the roots have formed, the glasses should be removed entirely. By August they will be fit to plant in their permanent situations at the distances noticed above. Should any of them send up flower-stems the first season, these should be cut off, and, indeed, the tops of the shoots had better be all so served at planting, or soon afterwards, to cause them to become bushy and compact. In gathering green sage for use, cut off the tops and side-shoots neatly; and when gathering for drying, let the flowers be nearly expanded, and cut off the young shoots only, in a neat manner, that the old plants may sustain no injury. Keep the ground clear of weeds, and stir amongst the plants frequently, but apply no manure whatever.

The common clary sage is raised from seed, and also from cuttings, which are to be treated like the last; while the hormium clary, or annual sage, is to be propagated by seeds only. Sow in March in drills 1 inch deep, 15 inches row from row, thinning out the plants as they advance to a foot apart. Neither of the latter need be grown to any great extent; from

a dozen to twenty plants will be sufficient for most families. The common sage, however, should be grown to about three times that extent. In very cold and damp situations, a very proper situation for common sage is an elevated rockwork, or the top of an old wall, where it may be quite dry, and fully exposed to the sun. In some situations it requires partial shelter during severe frosts, and for this purpose may be protected by covering it with branches or dry fern fronds. Protecting the roots, in most places, by a covering of rotten tan, leaves, or sifted coal-ashes, is very beneficial.

The European names of the common sage are—Sauge in French; Salvia in Italian and Spanish; Salva in Portuguese; Schalweja in Russian; Szalwia in Polish; Salbey in German; and Salie in Dutch. Those of common clary, Orvale in French; Schiarea in Italian; and Scharlachkraut in German.

*Balm* (*Melissa officinalis* L.) belongs to the natural order Labiatae, and to the class Didynamia and order Gymnospermia in the Linnæan arrangement. The generic name is derived from *Melissa*, a bee, from the abundance of honey that bees gather from it. A native of the south of Europe, and introduced into Britain in 1573. The plant, in its green state, has an agreeable odour of lemons, and an austere and slightly aromatic taste, and hence is sometimes employed to flavour certain dishes in the absence of lemon-thyme.

“It has also been called *apistrum*, from *apis*, a bee, on the same account; and it is still the custom to rub the bee-hives with balm and sugar, or honey, previous to taking a swarm—a practice,” as Phillips correctly enough observes, “which certainly appears to have the effect of attaching the colony to its new settlement.” Pliny notices this method of securing the bees in his time, and says that, where there is plenty of balm in the garden, there is no fear of the swarms straying. He tells us, also, that it is a good remedy for the sting of bees and wasps, &c.—a practice also still continued. The only other domestic use for which this plant is employed is in making cool tankards, balm wine, and balm tea. It is a perfectly hardy perennial plant, readily increased by division of the roots, either in autumn or spring. Set the plants a foot or 15 inches apart. They continue for several years, and adapt themselves to any ordinary garden-soil. Cut the crop when coming into flower, and dry as recommended for mint. The young leaves are the parts employed for making balm wine, and these are produced during the greater part of the summer. The dried plant loses nearly all that agreeable odour of lemons which the young green leaves possess.

The European names are—La melisse in French; Die melisse in German; Melisse in Dutch; Melissa in Italian, Portuguese, and Russian; Melisa in Spanish and Polish.

*Mint*.—*Mentha viridis*, green spearmint; *Mentha piperita*, peppermint; and *Mentha Pulegium*, Penny-royal—are the sorts cultivated

in gardens. They belong to the natural order Labiatae, and to the class Didynamia and order Gymnospermia in the Linnæan arrangement. They are all natives of Britain. The generic name is derived from *Mintha*, daughter to Co-cytus, who, according to the heathen mythology, was changed into this plant; the specific name, *Pulegium*, from *Pulex*, a louse, which animal it was thought to drive away. Mint and balm are said to be amongst the earliest medicinal plants selected by man. The young leaves of *M. viridis* are used in spring salads, and in acid sauce, with roasted lamb; it is boiled with green pease; it is generally used in pea-soup, and is relished by many in other soups also. As all do not, however, participate in the same taste for it, it should be served at table in a pounded state, so that each may help himself, according to taste. *M. piperita* is chiefly used for distillation; the leaves of *M. pulegium* are used in different branches of cookery.

It is propagated by division of the roots, the smallest portion of which will grow by removing off-sets or young shoots in spring, with a fragment of root attached to them—and in extremity, by cuttings of the stems. The first is the usual and best mode. Penny-royal is best increased by dividing the old plant into small pieces. It should be planted either in spring or autumn, before the plants begin to grow, or after vegetation has ceased, in drills drawn a foot asunder, and 2 inches deep. Select the youngest and strongest roots from amongst the old, and lay them lengthwise in the drills, and cover them over. When off-sets are employed, remove them from the sides of the old plants in spring, when about 3 inches high, and set them in drills as above, 6 inches apart in the rows. Cuttings of the young stalks taken off in June, and planted like off-sets, and at a like distance, will be established by autumn. Penny-royal should be planted in spring, at the same distances as the above, preferring a dampish situation.

Young plants recently set will be improved in growth by occasional waterings, and especially penny-royal, particularly during dry warm weather. Keep the beds clear of weeds by hand-weeding, for, from the nature of the plants, their roots running in all directions near the surface, hoeing cannot be applied. Old heds should have a top-dressing of light soil or rotten tan laid over them every autumn, to the depth of 2 inches: in this the young roots seem to luxuriate. It also preserves the buds during winter, and causes them to spring earlier in spring. This should not, however, be applied to penny-royal. In some soils the mints will continue for years, in others it is well to make new plantations every second or third year. At the end of summer cut over all the remaining stems close to the ground before top-dressing. Cut the alleys off at the same time, and gather out all extending roots, so as to restrain the plants within their proper bounds.

A moist loose soil is the most proper for the spear and pepper mints, while a strong moderately-moist soil is more fitting for penny-royal; all of them naturally grow in situations which

are occasionally irrigated or flooded by water. None of them require manure.

For medical purposes they should be gathered just as the flower appears; but for obtaining the essential oil, the flowering plant is preferred. In both cases, as well as for drying for culinary use, they should be cut when quite dry, and tied up into small bundles, and suspended in an apartment with a temperature of from 60° to 65°. By this means the agreeable flavour and green colour are preserved. Some gardeners place this, as well as most other herbs, in strong wooden boxes, and subject the contents to considerable pressure by loading them with weights, or by the application of a screw, so as to compress them into solid masses. This is done with a view to prevent the air from acting upon them, and destroying their aroma. The operation is carried on in a high temperature, and the boxes kept afterwards in a dry room. Others again dry them quickly by suspending them in a very warm apartment; and when sufficiently dry, reduce them down to a fine powder, which they keep in wide-mouthed glass bottles with glass stoppers.

*Forcing.*—In most families green mint is in demand throughout the winter; and, to provide for this, young healthy roots should be taken up and planted in shallow pans or boxes, in rotten tan, or light rich sandy soil, and placed in a pit or vinery, with a temperature of from 55° to 65°. It is important that a sufficient stock for the contemplated demand should be potted in autumn, or a portion of the old beds covered with litter to keep out the frost, so that they can be readily got at when wanted. Place the roots pretty closely together, and when one gathering of the young shoots has taken place throw them away, and introduce others. To keep up a constant supply, set the first set of pans or boxes into heat by the 1st of November, in number or extent corresponding to the demand; and set in to a similar extent every fortnight, until the end of February, after which a supply may be expected from the beds, by placing a few hand-glasses over a portion of them. Supply the roots placed in heat with abundance of water, and keep the plants as close to the glass as possible.

The mints are seldom annoyed by insects; the *Uredo labiatarum* Dec., a parasitic fungus, a sort of mildew common to all the Labiatae order of plants, often appears upon the leaves, but seldom to an extent to be injurious.

The European names of mint are—*La menthe* in French; *Die munze* in German; *Munt* in Dutch; *Minta* in Italian and Spanish; *Miata* in Russian; *Mietka* in Polish.

*Costmary* (*Balsamita vulgaris* W.) belongs to the natural order Compositae, sub-order Anthemideae, and to the class Syngenesia and order Superflua in the Linnæan arrangement. The generic name is derived from *Balsamon*, balm, from its strong balsamic smell; the English name *Costmary* from *Costus*, an aromatic shrub, and *Mary*—the Virgin Mary's *costus*. From its being put into ale, was derived the old English name of *Alecost*. A native of Italy, from whence it was introduced to Britain in 1568.

It is sometimes put into salads, but seldom asked for. It is a hardy perennial creeping-rooted plant, easily propagated by division of the roots, and succeeds well in any ordinary garden-soil.

Its European names are—*Coq-des-jardins* in French; *Die frauenmunze* in German; *Tuinbalsam* in Dutch; *Costo-ortense* in Italian; *Heirba de Santa* in Spanish; *Balsmita* in Portuguese; *Hanegræs* in Danish; *Svensk salvia* in Swedish.

*Tansy* (*Tanacetum vulgare* L.) belongs to the natural order Compositae, sub-order Anthemideae, and to the class Syngenesia and order Superflua in the Linnæan arrangement. The generic name is altered from *Athanasia*, itself a word which signifies a plant which does not perish, or an immortal plant. Indigenous to Britain, and an old inhabitant of our gardens. In Gerard's time, cakes were made of the young leaves in spring, mixed with eggs, and were called *tansies*. It was much used formerly during Lent, to correct the effects of eating salt fish; and cakes were made at Easter time and offered to visitors, a custom still kept up in many parts of England. At present it is chiefly used to flavour a peculiar pudding, called *tansy pudding*. The leaves are also used in omelets, and the curled variety for garnishing by those who like the smell. A hardy perennial plant of easy culture, spreading rapidly, and readily propagated by division of the roots. Like *costmary*, a plant or two is sufficient for a small garden. Roots of it potted in autumn and placed in slight heat, will afford a supply during winter; and for Lent use it should be so produced.

It holds a place in many cottage gardens, and is more used by that class than by any other. The European names are—*Tanaisie* in French; *Der rheinfarn* in German; *Reinwaar* in Dutch; *Tanaceto* in Italian and Spanish; *Tanasia* in Portuguese; *Dikaja riabina* in Russian; and *Wrotecz* in Polish.

#### § 4.—BASIL, SAVORY, ETC.

*Basil*.—*Ocimum Basilicum* L. (the sweet or larger basil), and the *O. minimum* L. (the bush or least basil), are both cultivated in all first-rate gardens. They belong to the natural order Labiatae, and to the class Didynamia and order Gymnospermia in the Linnæan arrangement. The generic name is derived from *Oso*, a smell, from their powerful scent. They are both natives of India: the former was introduced in or before 1548, and the latter in 1573. These are the two sorts cultivated in Britain, while *O. gratissimum* is cultivated in China as a culinary plant, and is also a native of the East Indies, and being a shrubby stove-plant, deserves our attention more than appears to have been bestowed upon it, more especially for winter use, when the annual sorts are so difficult to grow: a plant known from the earliest ages of Grecian history. "The leaves and bractæe, or leafy tops, are the parts gathered; and on account of their strong flavour of cloves, they are often used in high-seasoned dishes, as well as in soups, stews, and sauces, and a leaf or two is sometimes introduced in salads."—*Sub. Hort.*

p. 691. No turtle-soup is fit to present at a London civic feast without its due amount of basil seasoning. Phillips remarks that, during the reigns of Queen Mary and Elizabeth, farmers had learned to compliment their landladies when they visited their farms, and grew basil in pots to present to them. Tusser, in his "Five Hundred Points of Good Husbandry," has not failed to satirise this servile custom.

Being tropical annuals, they are raised annually from seed. In the southern parts of England the seed is sown on warm borders. In the north of England and Scotland, generally, it is sown in pots placed in a moderate temperature, and transplanted in May or June, according to the situation. In families of the highest grades, green basil is required throughout the year. For winter supply, seed should be sown in flat pots or boxes every fortnight, from the beginning of November to the end of March. From the first of April to the end of July, in England, it should be sown once a-month, and that upon the warmest and driest border the garden affords. In Scotland, it is better to sow at the same periods, with a view to transplant afterwards into the open garden; but in many cases it must be grown under glass.

The seed is small, therefore the surface should be rendered smooth, whether in pots or in the open borders. Sow thin, when the crop is to be grown without transplanting, which should be the case with such as are grown in pots, during winter; cover to the depth of a quarter of an inch; keep the soil rather dry than otherwise, and thin out if too crowded. The plants may be used when from 2 to 3 inches in height, therefore progressive thinnings may take place; and should the plants be thicker than is deemed expedient, a portion may be carefully taken up, and transplanted into other pots or boxes, where they will attain the height of 3 or 9 inches. Those grown in the open border, if the soil is light and rich, and the situation favourable, will, if set at the distance of a foot or 14 inches apart, cover the ground, and assume the appearance of dwarf stocky bushes. When the plants are just showing flower, they should be cut over by the ground, and dried as speedily as possible, either as recommended for mint, &c., p. 237, or otherwise, so as to retain the green colour, as well as a portion of the agreeable aroma for which it is so much valued. When sufficiently dry, it should be rubbed down to a fineish powder, and kept in wide-mouthed bottles, with glass stoppers, for winter use; but, like most other odoriferous plants, it loses much of its flavour when dried, and hence cooks always prefer it in the green state. The treatment of both sorts is the same.

The European names are—Basilie in French; Basilikum in German; Basilicum in Dutch; Basilico in Italian; Albahaca in Spanish; Alfavaca in Portuguese; Wasilik in Russian; and Bazylika in Polish.

*Savory*.—*Satureja montana* L. (winter savory), *S. hortensis* L. (summer savory), *S. capitata*, (headed savory), *S. viminea* L. (twiggy pennyroyal savory). The two latter—the first a native of the Levant, introduced in 1596, and the

second a native of Jamaica, introduced in 1783—are seldom cultivated in Britain, although both are much used in their native countries. The two former are, or should be, found in every garden: they belong to the natural order Labiatae, and to the class Didynamia and order Gymnospermia in the Linnæan arrangement; they are both natives of the south of Europe: the former was introduced in 1562, and the latter in 1652. The generic name is derived from *Ssatar*, the Arabic name for all labiate plants. The winter savory is an aromatic annual plant. The winter savory grows to the size of a small shrub, when planted in a poor dry soil; but in rich earth its pores become too full of moisture to stand the severity of our winters: both these are noticed by Virgil, among the fragrant herbs and shrubs that should grow near the bee-hive. Although the above dates of their introduction are given, it would appear by Gerard that they had been in use long before; and, with other Italian herbs used in Roman cookery, it is not improbable that they were introduced by the Romans themselves, and continued in the monastic gardens.

The perennial sort, *S. montana*, is propagated by cuttings taken from the young side-shoots in June, placed under a hand-glass on a shady border. The cuttings should be about 2 inches in length; and when they are rooted should be transferred to a nursery-bed, in a more warm and exposed place, to gain strength, so that they may be set out in their permanent place by the beginning of September. They should be planted in rows, 18 inches apart, and the plants set a foot apart in the line. They will continue for many years in a favourable climate and dry soil; but as they are apt to become straggling and unsightly, new plantations should be made every five or six years. In cold situations they demand slight protection during severe winters. It may also be propagated by seed, but the plants are longer in coming into use.

The annual sort *S. hortensis* is propagated by seed, which should be sown in warm localities in April; but in colder places it is better to sow in pots placed in a gentle heat, and transplant in June. That sown in the open air need not be transplanted if sown in drills half an inch deep and a foot asunder, if thinned out to 6 or 8 inches in the rows.

The perennial sort should be cut for drying just as the flowers are opening, and the annual one when in the same state, and dried and preserved as noticed for other odoriferous herbs. Both are used during summer in a green state. They were both formerly used in the composition of cakes and puddings, but are now chiefly employed in seasoning sausages, force-meats, and sometimes in soups; occasionally in salads—a use the Romans were well aware of.

The European names are—Sarriette in French; Die saturei in German; Keul in Dutch; Santoreggia in Italian; Ajedrea in Spanish; Segureilha in Portuguese; Tschaber in Russian; Ozabr in Polish; and Saer in Danish.

*Marjoram*.—*Origanum vulgare* L. (common marjoram), *O. heracleoticum* L. (winter sweet marjoram), *O. Marjorana* L. (sweet or knot-

ted marjoram)—belongs to the natural order Labiatae, and to the class Didymia and order Gymnospermia in the Linnæan arrangement. The first is indigenous to Britain, and common on dry chalky wastes; the second is a native of the south of Europe, and was introduced in 1640; the third is a native of Portugal, introduced in 1573; and a fourth, *O. onites* (pot marjoram), a native of Sicily, was introduced in 1759. The generic name is derived from *Oros*, a mountain, and *ganos*, joy—as if they were the joy of the places where they naturally grow. Common marjoram is a hardy perennial plant, readily propagated by division; and although it will continue for many years in most soils, a new plantation should be made every second or third year, setting the plants about 15 inches apart; and the operation may be performed in autumn or spring. Winter sweet marjoram is also a pretty hardy perennial, seldom, however, ripening its seed in this country; it is therefore, in general, propagated by cuttings, treated as we have recommended for savory: it requires a warm exposure and a dry soil. Sweet or knotted marjoram is a hardy biennial, rarely ripening its seed in this country; it should be treated as an annual, and sown every year; it should be sown in March, on a slight hot-bed in Scotland, but in England it is usually sown on a dry warm border in April. In the former case it should be transplanted, about the beginning of May, to a warm dry place, setting the plants in rows 15 inches asunder, and 9 inches apart in the line. The pot marjoram is a sufficiently hardy dwarf half-shrubby plant to stand our ordinary winters in the open border; it should, however, be propagated every third or fourth year by cuttings for new plantations, and treated like winter sweet marjoram.

The leaves and tender tops of all the marjorams are the parts used; they are in constant demand, being used in soups, made dishes, and other culinary preparations. Seeds of all the varieties may be obtained in the seed-shops; and plants, with all other sweet herbs of a perennial character, may also be purchased—and where the quantity required is small, it is the most proper way. A quarter of an ounce of seed is sufficient for most ordinary gardens, and the same may be taken as the average quantity for most other herbs of the same description; they are all cut as they come into flower, and should be preserved as already recommended. When grown from seed, sow in drills, 9 inches apart and half an inch deep, in light finely-pulverised soil; from six to twelve plants of each of these will be sufficient for a small garden.

The leaves of common marjoram are used in many places as a substitute for tea, and also, along with those of *O. Majorana*, form ingredients in cephalic snuff. According to Forskahl (p. 59) the latter species derives its name from *Marjamie* (maryamnych), its Arabic name. The European names of the marjorams are—La marjolaine in French; Der majoran in German; Mariolein in Dutch; Maggiorana in Italian; Meiorana in Spanish; Macran in Russian; Mai-eran in Polish.

*Anise* (*Tragium anisum*, Spr.—*Pimpinella*

*anisum* L.) belongs to the natural order Umbelliferae, sub-order Orthospermae, and tribe Ammineae, and to the class Pentandria and order Dignia in the Linnæan arrangement. The generic name is derived from *Tragos*, a goat, from the resemblance in odour to the smell of that animal. Linnæus's original name of *Pimpinella* has been altered, according to himself, from *Bipennula*—twice pinnate, in allusion to the leaves. *Anisum* is derived from *Anysun*, its Arabic name. It is a native of Egypt, introduced in 1551. Being an annual, it is sown yearly in April in drills, three quarters of an inch in depth and 15 inches asunder, and the plants thinned to a foot apart in the rows. A deep light soil is most proper. The seeds are used for distillation and expression, and imported in large quantities from Malta and Spain. They are also used in confectionary, and the green leaves in salads, and for seasoning and garnishing like fennel. The seed should be sown where the plants are to remain, as it does not succeed very well by transplanting. They are best raised on a slight bottom-heat for the climate of Scotland, two seeds in each pot of the 60 size, and in May turned out with the balls entire. In England this care is not requisite. Gather the crop for its seed when they are ripe, and during summer the young side-leaves will afford abundant supply for other purposes.

Its European names are—Anis or Boucage in French; Kleine bibernel in German; Kleine bevernel in Dutch; Pimpinella sassifraga in Italian; Pimpinella blanca in Spanish; Pimpinella branca in Portuguese; Bedvenez in Russian.

*Angelica* (*Angelica archangelica* L.) belongs to the natural order Umbelliferae, sub-order Orthospermae and tribe Angeliceae, and to the class Pentandria and order Dignia in the Linnæan arrangement. The generic name is derived from its supposed angelic virtues; its specific name from *Arch*, superior—an augmentative prefix: indigenous to England. Though only a biennial, it may be made to continue several years by cutting over the flower-stem before it ripens seeds, in which case it immediately pushes out below. Considerable quantities of this plant are grown by the London gardeners in moist situations, and along the banks of ditches. It is cultivated for its leaves and the tender flower-stalks, which were formerly blanched like celery. In the north of Europe the leaves and stalks are eaten raw, or boiled with meat and fish. In England and France the tender stems, stalks, and midribs of the leaves, cut in May, are candied by the confectioners, and a second crop will be produced the same season. If the stalks are allowed to flower, seed will be abundantly produced, which should be gathered as it ripens, as it soon sheds itself.

The seeds are sown in August, or indeed as soon as they ripen, to have the advantage of stronger plants in spring than if sowing were delayed to that time. Indeed, all biennials should be sown as soon as their seeds are perfected. When the plants are about 6 inches high, take them up carefully by loosening the ground about and under them, as they have

long tap-roots ; plant in moist deep ground, for this plant is half an aquatic, and set them in rows 3 feet apart and the plants 2 feet distant in the line, for they are tall and strong growers. They should not be cut the first year, but in the second they will be in fine condition ; and if the first cutting take place in May, a second crop will be obtained ; and thus on for several years, if the plants are prevented from running to seed, after which they must be cut down and a new plantation formed. Twelve plants will be enough for a small garden, and half an ounce of seed sufficient. They are sometimes increased by taking side-slips from the edges of the roots, but this is only a make-shift mode. The seed will keep for three or four years.

The European names are—Angelique in French ; Die angelika in German ; Engelwortel in Dutch ; Angelica in Italian and Portuguese ; Anjelica in Spanish ; Angelika in Russian ; Dziejiel ogrodny in Polish.

*Caraway* (*Carum carvi* L.) belongs to the natural order Umbelliferae, sub-order Orthospermae, and tribe Ammineae, and to the class Pentandria and order Digynia in the Linnæan arrangement. The generic name is derived from *Caria*, in Asia Minor, of which the plant is a native. It is now accounted a native of Britain, but the origin of its name, and the positive manner in which Pliny mentions from whence it sprang, refute this opinion. It is more than probable the Romans introduced it into Britain, as well as sundry other plants which modern British botanists have claimed as being indigenous, or absolute natives, without giving due consideration to the possibility of their having only escaped from gardens, and become so far naturalised as to grow without culture. That shrewd old botanist Gerard makes no mention of its being found growing wild in England, but says it grows abundantly in Germany and Bohemia "in fat and fruitful fields." Ray is the earliest author we have found who thought it a native, and states that "it grows wild in several places in Lincolnshire and Yorkshire ;" but Ray flourished about a century after Gerard, who was born in 1545, while Ray was engaged in pomological matters so late as 1688. This plant is cultivated in gardens for its under leaves, which are sometimes put into soups, and the young ones often into salads, and in former times the roots were eaten as parsnips. It is largely grown, particularly in Essex, for the seed, which is used for distillation and confectionary purposes. The seeds are used by cottagers to mix with their bread, and the Dutch introduced it into cheese. Unless for the seed, three or four plants are sufficient for a small garden.

It is propagated by seeds, which should be sown in autumn, as soon as they are ripe, in drills half an inch deep and 2 feet asunder, thinning out the plants to 18 inches in the lines. Like all aromatic plants, a poor light, but in this case a deep, soil should be chosen. A quarter of an ounce of seed is sufficient for most gardens.

The European names are—Le carvi in French ; Der kummel in German ; Karwey in Dutch ;

il Carvi in Italian ; Alcaravea in Spanish ; Alcaravia in Portuguese ; Timon in Russian ; Kamy in Polish ; and Kommen in Danish.

*Coriander* (*Coriandrum sativum* L.) belongs to the natural order Umbelliferae, sub-order Coilospermae, and tribe Coriandreae, and to the class Pentandria and order Digynia in the Linnæan arrangement. The generic name is derived from *Koris*, a bug, from the smell of the leaves. Indigenous to England, in corn-fields. In gardens it is cultivated for the same purposes as chervil, the young tender leaves being used in soups and salads. It is propagated by seed, which should be sown in February, in light dry soil, in drills half an inch in depth and 15 inches apart, thinning out the plants to 9 or 10 inches in the lines. The plants soon run up to seed during summer ; therefore, where a constant supply is required, sowings should be made every month from February to July. Sowings made during August and September should be on a warm dry border, and be protected during winter with a frame and glass.

The European names are—La coriandre in French ; Der koriander in German, Dutch, and Russian ; Coriandro in Italian ; Cilantro in Spanish ; Coentro in Portuguese.

*Marigold* (*Calendula officinalis* L.—common pot-marigold) belongs to the natural order Compositae, sub-order Heliantheae, and the class Syngenesia, and order Necessaria, in the Linnæan arrangement. The generic name is derived from *Calende*, first day of the month, on account of its flowering monthly, or rather from its being observed to flower most about the Calends of every month. It is a native of the south of Europe, and was cultivated in this country prior to 1573. The flowers are used in broths and soups ; and in certain dairies they are put into the cream, before churning, to give the butter a better colour. In Holland, the flowers are dried for the purpose of being put into winter broths, and for this purpose are to be found in most grocers' shops throughout that country, packed tightly in barrels, and sold by the ounce, for few broths are made without them.

The common or pot marigold is a hardy annual plant, which should be sown in March or April, in any ordinary garden-soil, in drills 15 inches asunder and half an inch in depth. When the plants come up, thin them to 9 inches apart ; but all this depends, as it does in all similar cases, on the richness or poverty of the soil. The flowers will appear in June, July, August, &c., and should be gathered for use when expanded fully ; and for drying, when they are quite dry, and preserved as has been recommended for other herbs. As it is a showy flowery plant, and grown in most flower-gardens, for ordinary supplies, enough may be procured from that source—as the more the flowers are gathered, the longer the plant will continue in vigorous production.

The European names are—Le souci de jardin in French ; Die ringelblume in German ; Goudblœm in Dutch ; Calendula in Italian and Spanish ; Nogotki in Russian ; Nogietek in Polish. Two packets, each 3d., are sufficient for a medium-sized garden.

## CHAPTER IX.

### MEDICINAL PLANTS.

IN the olden times, when barbers exercised the art of phlebotomy, and gardeners were the "cullers of simples" and administrators of physic, medical herbs were much more attended to in private gardens than at present. A few, however, are still found deserving cultivation even in these, while hundreds of acres are dedicated to this article of produce, for supplying the faculty with the majority of them. A considerable trade is also carried on by itinerant herbalists, who find a ready market for those of indigenous growth.

*Chamomile* (*Anthemis nobilis* L.) belongs to the natural order Compositæ, sub-order Anthemideæ, and to the class Syngenesia and order Superflua in the Linnæan arrangement. Indigenous to many parts of Britain, growing generally in gravelly pastures. There is a double-flowering variety, in general cultivated in gardens; it is much more ornamental than the single, but much less efficacious as a medicine. In many parts of England the peasantry have what they call a chamomile seat at the end of their little gardens, which is constructed by cutting out a bench in a bank of earth, and planting it thickly with the double-flowering variety of this plant, on which they delight to sit, and fancy it conducive to health. The flower is also sometimes used in the manufacture of bitter beer, and, along with wormwood, made to a certain extent a substitute for hops. The flowers, which are the only part used of the single-flowering variety, have long been in high repute, both in the popular and scientific *Materia Medica*, and give out their properties by infusion in either water or alcohol. This plant delights in a poor, light, sandy soil, fully exposed to the sun, and is increased by dividing the larger or older plants into small pieces, which will readily grow if small portions of the roots be taken with them. March, April, or May is the proper season for planting, although, with a little care, the operation may be performed at almost any other season. The young plants should be set in rows 8 or 10 inches asunder, giving a little water until they take root; or they may be planted as edgings to walks, or employed to cover a poor barren bank. One plantation will last from five to eight years in a productive state. The flowers should be gathered when fully expanded, choosing a dry day, and, when

gathered, laid thinly on a piece of clean canvass, in a dry, airy, partially shaded place for a day or two; afterwards placed in a warm apartment to dry thoroughly; after which they should be placed in paper bags, or, better, in wide-mouthed glass bottles, tightly corked, and kept for use.

The French call it Camomille; the Germans and Dutch, Kamille; the Italians, Camomilla; the Spaniards, Manzanilla; and the Portuguese, Macella.

*Hyssop* (*Hyssopus officinalis* L.) belongs to the natural order Labiatæ, tribe Satureineæ, and to the class Dydynamia and order Gymnospermia. It bears nearly the same name in most of the European languages, which signifies a holy herb, or herb for purifying holy places. From the frequent mention made of it in Scripture, we may infer that it grew wild in Syria and Egypt. It was long in considerable repute as a popular medicine, but its use now in this respect is chiefly confined to domestic administrators. In French and Italian cookery, the tops of the young shoots are sometimes used in soups, but its principal use is for medical purposes.

It is readily propagated by seed, which should be sown in March or April, upon a dry warm border—the plants to be afterwards transplanted in June or July, either as edgings in small gardens, or in rows a foot apart, setting the plants 8 inches asunder. It is in general, however, increased by cuttings or slips, which should be taken off in April or May, and placed under a hand-glass in a somewhat shaded place. By August or September they will have struck root, and should then be planted out as above.

The plants bear cutting with advantage, and therefore should be pruned back as soon as the flower spikes, with a portion of the current year's growth, are cut off for drying; and this should be done when the flowers are about expanding. Tie them up in small bunches, and dry them as recommended for thyme, &c. The plant delights in a dry soil, and is quite at home when established on top of an old wall—which habitation can readily be secured for it by sowing the seeds between the joints of the stones or bricks. It is called Hysope in French; Isop in German; Isopo in Italian; Hysop in Dutch; Hisopo in Spanish; and Hyssopo in Portuguese.

*Wormwood* (*Artemisia absinthium* L.) belongs to the natural order Compositæ, sub-order Anthemideæ, and to the class Syngenesia and order Superflua in the Linnæan arrangement. Indigenous to Britain; found in neglected places. Several of the genus are included in the *Materia Medica*, but, according to Dr Thomson, our present subject is the only one of them deserving to be retained. A long list of its virtues is given in "London Dispensatory," p. 152. The seed is used by the rectifiers of British spirits, and it is largely cultivated about Mitcham in Surrey for that purpose. The whole plant is used as a substitute for hops in brewing, and for this purpose it is cultivated in cottage gardens. It is also grown in most gardens for the purpose of being chopped up along with rue, cress, and similar plants, and mixed with the food of young turkeys. Plants of it should be set in every poultry-yard, as it is exceedingly beneficial to them. It is a hardy perennial plant, readily propagated by division of the root, as well as by seed, and may also be increased by cuttings, treated as already recommended for other herbs. An infusion of the seed makes an excellent and safe stomachic, taken to the extent of a wine-glassful every morning, the same as chamomile. Three or four flowers of the latter, and half a tea-spoonful of the seeds of the former, infused in a pint of warm water, and taken when cold, is the proper quantity.

The European names are—Absinthe in French; Wermuth in German; Alsem in Dutch; Ajenjo in Spanish; Assenzio in Italian.

*Rue* (*Ruta graveolens* L.) belongs to the natural order Rutacæ and tribe Rutææ, and to the class Decandria and order Monogynia in the Linnæan arrangement. It long held a high place in medicine, but is now less regarded. It is grown in gardens, as stated in the last article, chiefly for the use of poultry, and is given them with advantage in cases of croup. A native of the south of Europe, and introduced prior to 1562. It is readily propagated by seed sown in March, and by cuttings planted in April or May. It delights in a poor, dry, calcareous soil, in which it will continue from eight to twelve years, if not cut down with frost, which sometimes happens, but seldom till the thermometer falls to 15°. In cold situations it should be planted in a sheltered place, at the bottom of a wall, or amongst large stones in a rockery. Formerly the English, as well as the Germans and Dutch, used the green leaves of rue in their ragouts. They were also used as a pickle, being first boiled and then preserved in vinegar, and were in that state esteemed a good sauce for meat. The celebrated antidote of Mithridates, king of Pontus, with which most medical students are familiar, and which has, with slight alterations, been in use for nearly nineteen centuries, is principally composed of this plant. The receipt will be found by a reference to "Phillips' Hist. of Fruits," p. 351. The European

names are—Rue in French; Raute in German; Ruta in Italian; Ruite in Dutch; Ruda in Spanish; Ruta in Russian; Rude in Danish; and Vinneta in Swedish.

*Liquorice* (*Glycyrrhiza* Tou; *Glabra* L.; *Liquiritia officinalis* Monch.) belongs to the natural order Leguminosæ, sub-order Papilionacæ, tribe Lotææ, sub-tribe Galegææ, and to the class Diadelphia and order Decandria in the Linnæan arrangement. The name is derived from *Glykys*, sweet; *Rhiza*, root. A native of the south of Europe, and introduced prior to 1562. A hardy perennial deep-rooting plant, requiring a deep, sandy, loamy soil, trenched to 2½ or 3 feet in depth, and manured if necessary. Propagated by cuttings of the roots, which cuttings should be taken from the small horizontal roots of established plants. These should be cut into pieces 6 inches long, and planted in rows 3 feet asunder, setting the cuttings 18 inches apart in the line. During the first year after planting the ground may be cropped with lettuce, turnip, or any other shallow-rooting, low-growing crop; and at the end of the first season cut down the stems close to the ground, and fork up the surface. The third or fourth year after planting, the roots will be fit for use. They should be dug up in autumn, taking care to open a deep trench along one side of the row, so as to get the roots out to their full length. When taken up, if grown for sale, they should be immediately disposed of to the brewers' druggists, as they are largely employed in porter brewing; or to medical druggists, who also use them in medicine. If for private use, they should be packed in sand in the root-cellar, like beet, parsnip, &c., till wanted.

The European names are—Zoethout in Dutch; Reglisse in French; Regaliz in Spanish; Suss-holz in German; Regolizia in Italian. It is chiefly grown in gardens for the saccharine juice obtained from the root by decoction, which is used as an emollient in cold and fevers.

*Elecampane* (*Inula helenium* L.; *Corrisartia helenium* Merat.) belongs to the natural order Compositæ, sub-order Carduacæ, division Vernoniaceæ, and to the class Syngenesia and order Superflua in the Linnæan arrangement. *Inula* is a corruption from *Helenium*. Indigenous to Britain, found in moist pastures in the south of England; one of our largest native plants, attaining a height of from 3 to 5 feet. It long maintained a place in almost every garden in Europe, but of late it has been less regarded. The root is the part used; it is thick, fusiform, and aromatic, and is used medicinally in a candied state. Propagated by seed, but more generally by offsets taken off in autumn, when the plant is done flowering. These planted 3 feet apart in a deep, rather moist soil, in a partially shaded situation, will be fit for use the end of the second year. The European names are—*Inule* in French and German; and *Inulo* in Italian.

## CHAPTER X.

### EDIBLE FUNGI.

#### § 1.—THE MUSHROOM.

*Natural history.*—The mushroom (*Agaricus campestris* Linn.) belongs to the natural order Fungi, tribe Hymenomyces, division Pileati, and class Cryptogamia, order Fungi, in the Linnean arrangement. The generic name *Agaricus* is derived from *Agaria*, a region of Sarmatia. A vast number of species are indigenous to Britain, and many are natives of other parts of the globe, chiefly, however, in temperate climates. The English name Mushroom is probably a corruption of Mousseron, the French name of a variety of the fungus called Champignon. The genus *Agaricus*, like all cryptogamic plants, are produced by seeds, but these are so minute as to require glasses of the greatest power to bring them within the power of human vision. The seeds are placed between the gills or thin flat plates situated under the cap or pileus, and when in a ripened state are discharged spontaneously in immense numbers in form of small minute granules, by which the species is propagated. These falling to the ground, or being blown about by the wind, become attached to the leaves and stalks of grasses and other plants; are taken into the stomach of certain animals, such as the horse, and pass through the intestinal canal uninjured in their vegetative property; or falling upon favourable media, become in time transformed into a white thready-like mucreous matter called spawn, which is capable of propagation; and ultimately, when placed in a proper degree of heat and humidity, of reproducing its species in the shape of perfect mushrooms.

*Use.*—Ignorance and prejudice are alike difficult to overcome, and this is perhaps in no case, in which the food of man is concerned, more clearly exemplified than in the case of the edible fungi with which our country abounds. Throughout the whole continent of Europe, profitable advantage is taken of them, so that in "France, Germany, and Italy they not only constitute the sole diet of thousands for weeks together, but the residue," Dr Badham remarks, "either fresh, dried, or variously preserved, in oil, vinegar, or brine, is sold by the poor, and forms a valuable source of income to many who have no other produce to bring into the market." So much importance is attached to the consumption of esculent fungi at Rome, that the government, in

1837, established an official inspector (*Ispettore dei Funghi*) to examine their qualities, and regulate their sale, which is conducted under the surveillance of the police, and a tax equal to a halfpenny sterling is imposed on every 10 pounds' weight.

In Poland and Russia above thirty sorts are eaten by the peasantry, not only in their fresh state, but dried in stoves, and preserved for winter consumption. The sorts generally used in Britain are, according to Sowerby, in his work on English Fungi, the truffle and morel, both of which are held in high estimation by epicures, and the true mushroom, the *Agaricus campestris* of botanists. The following species are occasionally eaten, and may be so with perfect safety—viz., *A. violaceus*, *A. pratensis*, *A. deliciosus*, *A. cinnamomeus*, *A. lactifluns*, *A. solitarius*, *A. cantharellus*, *A. aurentiacus*, *A. procerus*, *A. virgineus*, *A. orcades*, or fairy-ring mushroom, from their appearing in old pastures either in entire circles or parts of circles. To these Dr Badham adds, *Agaricus vaginatus*, *A. rubescens*, *A. excoriatus*, *A. prunulus*, *A. personatus*, *A. heterophyllus*, *A. virescens*, *A. ruher*, *A. piperatus*, *A. nebularis*, *A. fusipes*, *A. ostreatus*, *A. ulmarius*, *A. orcella*, *A. castaneus*, *A. Georgii*, *A. comatus*, *A. atramentarius*, *A. cibarius*, *Polyporus frondosus*, *Boletus edulis*, *B. scaber*, *Fistulina hepatica*, *Hydnum repandum*, *Morchella esculenta*, *M. semilibera*, (the esculenta and hybrida of Sowerby), *Helvella crispa* and *lacunosa*, *Peziza acetabulum*, *Bovista plumbea*, *Lycoperdon plumbeum* and *bovista*, all of the genus *Clavaria*. The above form the principal of the esculent fungi, and may all be eaten with perfect safety if taken while young or newly gathered. Hitherto the *Agaricus campestris*, of which, however, there are several sub-varieties, has been the species alone cultivated in Britain. That there are others deserving our attention, even in a cultural point of view, there is no doubt. Of these the following may be considered the most important.

*Agaricus prunulus* (Vitt.) is found only in spring, growing in rings on the borders of woodlands, at which time abundance of its spawn may be procured, and may be continued in the same way that the spawn of *A. campestris* is; namely, by transplanting it into bricks of loam and horse-dung, in which way it will keep for months. This mushroom is used both in its green and dried state, in which latter state it

constitutes what is called "Funghi di Genoa," and is preserved by being simply cut into four pieces, and dried in the air for a few days, when it is strung up and kept for use. It is not a common species in Britain.

*Agaricus procerus* (Scop.), one of the most delicate of all the mushroom tribe. It is very common in England, and held in high esteem in France and Italy. It is an autumnal species, and makes excellent ketchup.

*Agaricus exquisitus* (Badham), *A. Georgii* (Withering), often attaining the weight of 5 or 6 lb. Considered less delicate than *A. campestris* in Britain, but looked upon in Hungary as a special gift from the saint whose name it bears. Persoon describes it as superior to *A. campestris* in smell, taste, and digestibility, on which account, he says, it is generally preferred in France. It is found abundantly in many places, generally growing in rings, and reappearing for many successive years on the same spot; and although sometimes found in old pastures, is in general to be met with in thickets under trees.

*Agaricus deliciosus*.—Found during September and October growing under Scotch fir-trees and other pines; of medium size, yellowish, zoned with deep orange on top, somewhat resembling *A. torminosus*, a deleterious species, but readily distinguished from it, as its juice is, when fresh cut, quite red, afterwards turning green, while that of the latter is white and unchangeable. Sir James Edward Smith, in his "Tour," says, "The market of Marseilles exhibited a prodigious quantity of *A. deliciosus*, which really deserves its name, being the most delicious mushroom known." And Mr Sowerby is equally high in its praise, remarking, "I had one dressed; it was very luscious eating, full of rich gravy, with a little of the flavour of mussels."

*Agaricus personatus*.—One of our most common British mushrooms, appearing in October in circles, and sometimes growing in clusters amongst old pasture-grass. It has found its way into Covent Garden market under the name of Blewitts or Blue Hats.

*Agaricus oreades* (Bolt).—This is the well-known Champignon, abounding in most old pastures, appearing in succession for several months, generally growing in circles, and greatly abounding after rain has succeeded dry warm weather, that being the most favourable condition for the growth and extension of the spawn, and the former the best condition for the production of the perfect mushroom. Dr Badham thus speaks of this species: "Independent of the excellent flavour of this little mushroom, which is as good as that of most funguses, two circumstances give it an additional value in a domestic point of view—viz. the facility with which it is dried, and its very extensive dissemination. When dried, (two or three days' exposure to the air is generally sufficient to effect this), the *A. oreades* may be kept for years without losing any of its aroma or goodness, which, on the contrary, becomes improved by the process, so as in fact to impart more flavour to the dish than would have been imparted by the fresh fungus; though it is not to be denied that the flesh then becomes coriaceous, and less easy of digestion."

*Agaricus nebularis*, reappearing for years in the same spot, generally in October, considered lighter of digestion than any other sort.

*Agaricus comatus* and *A. atrimentarius* are employed for making ketchup, but should both be used in a young state. The former is found abundantly growing on stumps of trees, appearing both in spring and autumn; while the latter is found amongst grass in meadows and pastures, from spring till late in autumn.

*Agaricus virescens* (Schoeff.), *A. ruber* (Schoeff.), and *A. heterophyllus* (Fries.), are all of the edible section. The former, indeed, has been recommended for cultivating by M. Thore. It is not very abundant in Britain. Vittadini describes it as excellent, and much used by the peasants about Milan, and asserts also that it is eaten in England. According to Roques, it is much used in France, both in a fresh and dried state. *A. ruber* appears in great abundance in many places from July till late in autumn, and is both delicate and easy of digestion. The latter is considered by Vittadini, Roques, and Dr Badham as not surpassed in flavour by any other of the mushroom tribe. It is found during the summer months, and often in abundance, under elm trees in dense woods.

*Agaricus rubescens* (Persoon).—Found during summer and autumn in woods, particularly in those of oak and chestnut. It is one of the most delicate as well as one of the most common of our British species, and eminently deserving the attention of collectors as well as of cultivators.

*Agaricus oreella* (Bull).—Appearing occasionally during summer, but far more usually during autumn, amongst grass, in woods and pastures, growing either solitary or in groups, and sometimes in circles, frequently succeeding a crop of *A. oreades* and *A. prunulus*: a most delicate and safe species.

*Agaricus virgineus* (Wulf).—Found abundantly in many places; in old pastures during autumn; often in company with puff-ball, *Lycoperdon plumbeum*: indeed they are often gathered and eaten together.

*Agaricus piperatus* (Scop).—Found in woods, during July and August, but not abundant; is very extensively used on the Continent, both in its fresh and dried state; it is also preserved, for winter use, in a pickle of salt and vinegar.

*Agaricus fusipes* (Bull).—An excellent fungus, found in great abundance at the roots of old oak trees, particularly after rain, throughout both summer and autumn.

*Boletus edulis* (Bull).—A prejudice exists in Britain generally against the whole of this genus; nevertheless we have the testimony of ages that the ancient Romans were not only acquainted with this very delicious species, but also that they prized it exceedingly. Two species of *Boletus* are eaten, and highly approved of, on the Continent, namely, *B. edulis* and *scaber*. The genus is extensively found in Britain, principally during autumn, but also occasionally during spring and summer, chiefly in woods of oaks, pines, and chestnuts. Of its merits as an esculent Mr Berkeley thus speaks: "Though much neglected in this country, it appears to be a most valuable article of food; it resembles much in taste the

common mushroom, and is quite as delicate; it abounds in seasons when these are not to be found."

*Boletus scaber* (Fries.)—Found in similar situations to the last, but should be used in a fresh state, for when dried it loses much of its odour, and is both insipid and unfit for use.

*Cantharellus cibarius* (Fries.)—Found during summer in great abundance, and continuing, although in less numbers, till towards autumn. It appears to be local in its habitats; the neighbourhood of Chelmsford, in Essex, about Tunbridge Hills, and amongst moss under beech-trees in Burkhurst Park, are particularly famed for this highly-prized fungus: from these places the London demand is chiefly supplied.

*Hydnum repandum* (L.)—Found in woods, particularly those of oak or pine; sometimes gregarious, or in rings, at other times solitary.

*Fistulina hepatica* (Bull.)—Grows upon old oak and chestnut trees, appearing throughout the summer often in great abundance, varying in size and shape, often, when fully grown, measuring 5 feet in circumference. Shæffer designates this "fungus pauperibus esculentus," or poor man's fungus, because it is a great acquisition to the poor where it grows in plenty.

*Helvella lacunosa* (Afy.), and *H. crispa* (Fries.)—Found in woods, not unfrequently growing on the stumps of old trees; in flavour somewhat resembling the morel, for which they are sometimes substituted.

*Clavaria coralloides* (L.), *C. grisea*; *C. cristata* (Pers.); *C. rugosa* (Bull.), are all esculent fungi indigenous to our woods and damp shady places.

*Lycoperdon plumbeum* (Badham); *L. Bovista* (Pers.)—Both are common, during summer and autumn, in dry exposed pastures, sometimes growing solitary, but for the most part in groups, and are known by the name of puff-balls; five species are recorded as natives of Britain, and all are found wholesome to eat.

The above enumeration of esculent fungi is given chiefly upon the authority of Dr Badham, whose excellent work, "Esculent Fungi of England," with coloured figures, should be perused by every gardener. M. Roques, Paulet, Persoon, and Cordier, have published excellent treatises on the kinds fit for human food, as used in France, and the no less valuable work by Vittadini gives the kinds in general use in Italy. The testimony of such authorities should shake the prevailing prejudices existing in Britain against a more general use of this valuable tribe of plants.

Much of the effects produced by indulging in the use of mushrooms has arisen from the place in which they have been produced, as it is a well-known fact in Covent Garden, that mushrooms gathered from the open fields, or even grown artificially in gardens, on open beds, are preferred to such as are produced in dark ill-ventilated cellars. That mushrooms, when too old, and beginning to decay, become chemically changed, and may produce less agreeable sensations, is not to be questioned; but this in no wise affects the fact of their being as wholesome a diet as any other vegetable production used in its proper state. Steeping mushrooms in brine

or acetic acid, before cooking, robs them of whatever deleterious principles they may possess. The residue left is pure *fungine*, which is perfectly innocuous, and the subsequent process of cooking renders them easy of digestion. Spirits of wine and vinegar extract some part of the deleterious properties, and tannin decomposes the greatest part of it.

*Cultivation.*—The *Agaricus campestris*, or common mushroom, is the only species that has as yet been subjected to successful cultivation, although there can be little doubt that all or most of the terrestrial-growing sorts would submit to the same process, if their natural habitats were sufficiently studied, and their spawn collected and propagated. In this way the common mushroom was first brought under the control of man. The morel is said to have been occasionally cultivated, and Lightfoot asserts that he succeeded in producing it from seed. The truffle has been cultivated in Germany and Italy to a limited extent, an account of which will be found in the "Gardeners' Magazine," vol. i. p. 320, and vol. x. Of the conditions necessary to the successful cultivation of fungi, little that is satisfactory is known. Moderate heat and moisture seem to be the principal agents that excite the seeds, in the first instance, and bring the plants to a state of perfection afterwards. Some species, however, are produced in a very low temperature, but none without the necessary amount of humidity. That all fungi are originated from seed is incontrovertible. These seeds are called spores, and are quite invisible to the naked eye; indeed, under an ordinary microscope, they appear as mere particles of dust; nor is it until we employ magnifiers of very great power that either their colours or shapes can be determined. The seeds of all cryptogamic plants are produced in enormous numbers, compared with those of phanogamous ones; many, however, of them are abortive, and probably a greater number never reach a proper nidus on which they can establish themselves. The seed of the common mushroom, in falling from the gills when ripe, is no doubt wafted by the wind, and becomes attached to the stems, leaves, &c. of grasses and other herbage, and, notwithstanding their being taken up by such animals as the horse, the deer, and the sheep, pass through their intestines without undergoing any material change in their vegetative existence; and hence, in the dung of these animals, when placed together, and kept moderately dry, and brought to a slight state of fermentation, we discover the first stage of existence of the future brood of mushrooms. This is practically called spawn, and consists of a white fibrous substance, running like broken threads through the mass of dung, which appears to be its only and proper nidus. The successive development of the seeds or spores is thus described by Dr Badham: "When the spore ceases to be a spore, and to become a mushroom, the first thing it does is to send forth certain cotton-like filaments, whose interlacings entangle it completely, while they also serve to attach it to the place of its birth. These threads (like the spongioles attached to the roots of phanogamous plants) absorb, and bring

nourishment to the quickened spore, which then maintains itself entirely by intus-susception. All this takes place before the germ has burst, or the embryo fungus begun to develop its organs. In some instances these elementary threads are, like the ordinary roots of plants, spread out to a considerable distance under ground, forming here and there in their course small bulbs or tubercles, each of which in turn becomes a new individual; in others, and more commonly, these spores are sprinkled about unconnectedly, affecting certain spots only, which become so many small matrices, whereof each furnishes a crop. The union of many germinating granules, together with these connecting threads, constitutes mushroom spawn, or, as it is technically called, *carcyles*. Examined a short time after quickening, the spore (or seed) is found to have swelled out into a fleshy kernel, which, in puff-balls, truffles, and the uterine subterranean families generally, constitutes of itself the whole fungus: this only grows in size afterwards, the substance and original form remaining the same through the entire period of development. In those destined to live under the influence of air and light, this same rudimental nucleus gradually evolves *new parts*, and assumes a vast variety of forms (whereof each particular one is predetermined by the original bias imprinted upon every spore at its creation); and here there is a manifest analogy with the progressive development of new parts in the higher orders of plants. In such funguses as are wrapped up in a volva or bag during the earliest period of growth, this furnishes them not only with the means of protection, but of nourishment also. This volva, which is formed by the mere swelling out of the original fleshy bulb, when it has grown to a certain size, exhibits towards its centre the rudiments of the young fungus, of which the receptacle appears first, and all the other parts in succession. The embryo next taking to grow in its turn approaches the circumference of the volva, which, having by this time ceased to expand, is burst open, and sometimes with much violence, by the emerging amanite. As soon as the hymenium (or gills) has parted with its seed, which falls from it in the form of fine dust, the fungus, collapsing, either withers on its stem, or else dissolves into a black liquid, and so escapes to the earth." This fine dust, whether it be regarded as seeds, germs, or sporules, is undoubtedly the means by which reproduction is effected. Little attention has hitherto been paid to the production of mushrooms directly from seed, although the circumstance of many sorts appearing, year after year, in nearly the same spot, would lead us to suppose that this is owing to the seed of the previous year's crop being shed, and retaining its vitality until the natural season of its again reappearing. The investigations made by Messrs Dutrochet and Turpin, in tracing the cause of the reappearance of the agaric in the familiar phenomena known as fairy-rings, evidently strengthen such an opinion; and we doubt not that, were even artificial mushroom-beds kept in a fitting state as to humidity and temperature, and a sufficient number of mushrooms allowed to come

to full seed-ripening maturity, succeeding crops would be obtained for years by the same means, and on the same beds.

Nicol, writing practically on this subject, observes—"The cultivation of mushrooms is a process in gardening perhaps the most singular and curious of any. In the culture of any other vegetable, we either sow or plant something material—a seed, slip, or root, which we both see and handle; but, in the cultivation of the mushroom, we neither sow nor plant anything visible, at least to the naked eye. Yet it is certain that mushrooms are produced from seeds which naturally vegetate in the fields at certain seasons, and which may be made to vegetate artificially, at any season, by a certain process, and by a composition in which the dung of certain animals form the chief ingredient.

"The droppings of horses are found to produce mushrooms more plentifully and with greater certainty than the dung of other animals," and the higher fed they are the more certain is the result; for it is notorious that the droppings of these animals while at grass, or when fed on green food, do not produce mushrooms to the same extent. Next to the horse, the droppings of the deer and sheep are found most suitable, probably on account of the seed of the fungus being less affected by moisture while passing through their intestines, than they would be in passing through those of the cow; or, as probably, that they retain their vegetative powers better in the dry droppings of the former animals, after being voided, than they do in the moister ones of the latter. Or it may be that the seed passes through the stomachs of the former animals with less injury to their vegetative quality than through those of the latter, for assuredly all of them alike take into their stomachs the seeds in equal abundance along with their natural food. "The food of horses," as Nicol has suspected, "consisting mostly of corn and hay, may no doubt be more replete with the seeds of mushrooms than that of cows or other stock, which consists chiefly of green vegetables; but even the droppings of horses, when on grass or on tares, produce few or no mushrooms. This fact would seem to prove that either the seeds are collected in great numbers, and are better preserved by hay, or the straw and chaff of oats, than by green food; or that green food may have the effect of destroying them by its moistness in the stomach, or after passing through it." This appears to us to be the true *rationale* of the question, as the seeds of fungi will retain their vegetative power for months—nay, perhaps, for many years—if kept dry, as practically demonstrated by the care we take in keeping the spawn dry after it has been produced, and also that it is only in dry dung-hills, or in dry sheds or places under cover, that we find it most abundant in a natural state. "It may further be observed," Nicol continues, "that animal matter seems necessary to the vegetation of those seeds, or the spawn of mushrooms. Hence, we find them produced plentifully in old pastures, and in cattle-sheds, whether these be frequented by horses, cows, sheep, or by all of them. But the common mushroom, *Agaricus*

*campestris*, is never found in woods or fields from which cattle are completely excluded."

The production of spawn will be understood from the above;—it is to be looked for in a natural state during September in places where mushrooms are found indigenous, in the track of a mill worked by horses under cover, in riding-houses, or sheds where horses are wintered or have long had access to, and in places where horse-droppings have accumulated and been kept dry. It is also sometimes found in half-decayed dung-hills, hot-beds, &c.; but never in either of these, if very damp or saturated with water.

*Preserving natural spawn.*—The pieces should be retained as large as possible, and placed loosely in shallow hampers, or, if quite dry, in boxes kept in a dry place—here it will remain inactive for two or three years, or until it be required for spawning prepared beds; or broken into small pieces, and transplanted into properly prepared bricks or cakes—in which state again it may be kept for as long a period, or even for a greater length of time, if kept perfectly dry and in a moderate temperature.

*Propagating or transplanting spawn.*—For this purpose, at almost any season of the year, but more especially from the end of May to the end of September, at which period the spawn is naturally most active, a quantity of dry horse-droppings, sheep or deer dung, should be collected, and placed under cover; to this a little finely-chopped fern fronds or dry littering dung should be added; and to this, when well mixed together, add as much rich mellow loam as will make the whole mass, after being wetted sufficiently and thoroughly incorporated, assume the consistence of thick mortar or grafting clay. The use of the fern fronds, or short litter, is to hold the material together; and of the loam, to give the bricks or cakes greater consistency. When the whole is well beat up together, spread it out upon a smooth level floor to the thickness of about 3 or 4 inches. When partially dried, cut it into pieces with a sharp spade in form of bricks 9 or 10 inches long, and 5 or 6 inches in breadth. Leave it in this condition for a few days to dry, so that the bricks may be handled without breaking; turn them over daily, still further to add to their solidity; and when nearly dry, perforate their upper edges with holes 1 inch in diameter, and place in each a piece of spawn about as large as a walnut, and cover the orifice of the holes with a little of the prepared mixture, to prevent the spawn from falling out. Then build the bricks or cakes in an open manner, as brickmakers do in drying bricks, and cover the whole with a coating of dry stable-manure in a slight state of fermentation, to cause the spawn to run through the bricks. Where there is the convenience of a dry warm place, or if space can be spared in the mushroom-house, this operation may be advantageously carried on in it, keeping the temperature at from 55° to 60°. It will be readily ascertained when spawn has run through every part of the bricks, by breaking one or two through the middle, when, if in a good state, the spawn will appear like a fine white mould throughout the brick. They should then be laid by in a dry place till required, either for spawning the beds

or for breaking down for future propagation. Various modes have been practised for propagating spawn, both by transplanting it into bricks and causing it to run in large masses—the materials used for the most part being the droppings of horses, cows, deer, and sheep, either alone or incorporated with loamy soil. Some, however, have added pigeons' dung, leaf-mould, rotten tan, and others coal-ashes: the advantage arising from any of which it is difficult to comprehend, more especially of the latter. The best materials, there can be no doubt, are the droppings of horses, deer, or sheep; and all or either of these will form a proper nidus for the germination, if we may so call it, of the seeds of the mushroom, for in each of these the spawn is naturally found. But as all of these require some adhesive matter to cement them together, none is better than an argillaceous loam: this, however, should not be used in too large a proportion, for we have invariably found the spawn to run best when the nidus prepared for it is not too hard or compact.

*Procuring spawn artificially.*—Early in March, while the cattle are on dry food, procure two parts of cow-dung, one of horse-droppings, and one of sheep or deer's dung. Dry them under cover, and break the whole down, so that it may pass through a half-inch sieve; mix the whole together, and lay the mass up in a conical heap. In forming the heap, tread or beat it closely together, which will prevent too rapid a state of fermentation. The heat during the process should not exceed 55° or 60°—for the mushroom, in all its stages, is equally impatient of excess of heat and cold. If the process be carried on in a warm shed, possibly no covering need be applied, beyond that of an old mat or a little dry litter; if otherwise, a slight covering of warm littering dung should be laid over it, to promote and continue the necessary temperature above stated. In about four weeks the mass should be examined, to ascertain if the spawn has begun to run. This will be indicated by its appearance in the shape of white thread-like matter abounding in it. If this should appear not to be the case, then an additional covering of warm dung should be laid over it, to increase or revive the heat, which will, if the materials have been got together in proper condition, stimulate the spawn into one mass, ready for use. Sometimes the end is effected in three or four weeks, while at other times it will require double that time. Spawn thus produced is of excellent quality, but it will not keep so long as that made in the form of bricks.

Some spawn manufacturers, instead of planting the pieces in perforations made in the bricks, lay a course of them flat on the floor of a warm vinery, and sprinkle over them the fragments of other spawn-bricks, broken down on purpose; and on this another course of bricks; and so on alternately, until the whole is built into a solid mass. In a few weeks the spawn penetrates the whole mass, and may then be taken to pieces, and the bricks stored by in a dry place, where they will keep for years.

*Producing mushrooms without transplanting spawn.*—This is effected by making the bed a

whole mass of spawn at once; and although by this means the crop is not always so soon produced, it has the merit of continuing to bear abundant crops for a much longer period than that of beds made in the ordinary way. Nicol, an old but excellent authority, followed this practice, and says the difference of time between beds coming into bearing made in this way, compared to the usual manner, will be three or four weeks; but the advantage will be, that in the one the crop will only last a few weeks or months, while in the other he has had them producing all the year over, and sometimes two years. His mode of proceeding was, after laying a foundation "of ashes, stone chips, gravel, or brickbats, so as to keep the bed quite dry and free from under-damp, to lay over it a course of horse-droppings, 6 inches thick. These should be new from the stable, and must not be broken, and the drier the better. They may be collected every day, until the first layer be formed to the above thickness, but they must not be allowed to ferment or heat. In the whole process of making up, the bed should be as much exposed to the air as possible, and it should be carefully defended from wet, if out of doors. When this course is quite dry, and judged to be past a state of fermentation, cover it to the thickness of 2 inches with light dry earth—if sandy, so much the better. It is immaterial whether it be rich or not, the only use of earth here being for the spawn to run and mass in. Now lay another course of droppings, and earth over, as above, when past a state of fermentation; then a third course, which earth over in like manner. This finishes the bed, which will be a very strong and productive one, if properly managed afterwards. Observe that in forming the bed it be a little rounded, in order that the centre may not be more wet or moist than the sides. If it be made up against a wall in a cellar, stable, or shed, it should have a slope of a few inches from the back to the front, less or more, according to its breadth. I have sometimes," he says, "been contented with two courses, as above, instead of three, and often, when materials are scarce, have made them up slighter, thus—three 4-inch courses of droppings, with 1 inch of earth between each, and a 2-inch covering at top. Such a bed as this I have had produce for ten or twelve months together; but very much depends on the state of the materials, and on the care taken in making it up, also on the after management. The droppings of hard-fed horses only are useful. Those of horses on green food will of themselves produce few or no mushrooms. This I have proved in more than one instance, and I have moreover found that the richer the keep of the horses, the more productive are their droppings. I have made up beds from farm-horses fed partly on hard and partly on green food, and from carriage or saddle horses fed entirely on corn and hay—treated them in the same way in every respect—and have found, not once, but always, those made from the latter the most productive."

In any of these ways an abundance of spawn may be procured, the production of which is the first step in mushroom culture. To those, however,

who have not ample means and proper material at command, we would say, procure the spawn ready made from a respectable nurseryman. It varies in price from 5s. to 8s. per bushel. That made by the London spawn-manufacturers we have always found to be the best. The demand is such, that the making of spawn bricks for the supply of the London trade is now carried on by parties who do little or nothing else.

*The formation of the beds.*—The modes of this are as different as the production of the spawn. A mere recapitulation of them would tend to little practical advantage, for all are aiming at the same end, although they make use of very different, and often very opposite means. The essential points to be regarded are, proper material, good spawn, moderate temperature, uniformity of humidity, according to the state of the beds or crop—as while the spawn is running, and until it is desired that the crops shall appear, they can hardly be kept too dry. Afterwards they require a greater amount of moisture, and this, particularly during winter, applied in a tepid state. Darkness has, by some, been deemed essential; light is admitted freely by others, and of the propriety of so doing there can be but one reasonable opinion.

The London market-gardeners, who grow largely for the supply of the market (even to the extent, as computed by Mr Cuthill, of not less than ten acres being continually under this crop in the immediate vicinity of London alone), form their beds in ridges in the open air, and in manner following: "As the stable-manure is brought home from the London stables, the short material is shaken out of it, and the long stringy part is kept for the purpose of covering, as well as for forming the interior of the ridges. The manure is not allowed to heat before it is put into the beds, if that can be prevented—for previously heated material does not produce so fine mushrooms. The fresher the horse-dung is, the longer will the crop last; and every one who makes up beds with unheated droppings knows how superior they are to fermented manure. If this is properly attended to, it does not signify what kind of mould is used for surfacing the beds with. When the interior temperature of the ridges gets down to 80°, it is spawned with pieces about 2 inches square, placed about 1 foot apart. The bed is then moulded over 2 inches thick, pressed with the feet, and afterwards beaten with the back of a spade. It is then watered and beaten again with the spade, and smoothed down. The more the mould is pressed, the finer the crop is, and the more solid the texture of the mushroom. This and green unbeated manure constitute the two grand secrets in mushroom-growing. Beds made up in this way want but little watering, and when they are watered, it ought to be with liquid manure. The ridges are covered with straw and mats. Such ridges as these are continually being made, and when well formed they last for two or three months in good bearing."

Many think mushrooms produced on ridges, in the open air, superior to those grown in houses; but we think, when sufficient light and air are admitted, that they are as good in the

one way as the other. Of one thing there can be little doubt, that in properly constructed houses, and under good management, the crop may be calculated upon with much greater certainty than when exposed to the vicissitudes of open-air culture, unless it may be during the months of July, August, and September, their natural season of growth. Beds formed in the open air should always be constructed of open littering material, as recommended above as being the London practice; for if otherwise, the spawn would be extremely liable to be destroyed by excess of moisture. To guard against this in properly constructed mushroom-houses (as figs. 660 to 670, vol. i.), the shelving should (as recommended, p. 467, vol. i.) be perforated with abundance of holes, if formed of iron plates, slate, or pavement; and if of wood, the boarding should be in narrow slips, at least 1 inch apart. These perforations and openings not only secure the beds against the bad effects of damp—to which they would be exposed, if laid in either material without such precaution—but they afford an opportunity for the mushrooms to protrude through them, and often yield nearly as good a crop from the bottom of the bed as from the top.

*The German method of forming mushroom-beds* on shelves, in houses constructed for the purpose (vide fig. 660, vol. i.), was introduced into this country, about 1814, by the late Mr Oldacre, and may be considered the basis on which most subsequent forms have been founded. Prior to that period they were in general formed in shape of ridges set on the floor of a covered shed, and in no way differing from those built in the open air, or in form of sloping banks resting against a wall—in both ways occupying a great space, in proportion to the surface they presented, for the production of the crop. The material used by that excellent cultivator was the droppings of horses shaken out of the litter before it had been exposed to fermentation or wet, retaining with the droppings about one-fourth in quantity of the shortest portion of the litter; to which he added about one-fourth dry turfy loam, to consolidate the mass, when beaten together, into a more solid and compact body than if only droppings and litter alone were used. On the solidity of such beds much of their success depends, as will be sufficiently apparent when we consider that they seldom exceed 7 or 8 inches in thickness. When a sufficient quantity is collected and mixed, as above, to form the bed, it is spread over the bottom of the shelf, or on the surface of the floor of the house (the lowest bed being placed under the first tier of shelves, and rendered perfectly dry below), to the thickness of 3 inches of the prepared compost. This is beaten with a wooden mallet into a close compact body, and over it another layer of the same thickness, which is in like manner beaten closely down; and so on, until the required height of bed is attained, which is in general 7 inches, leaving the surface as smooth and even as possible. "Reducing the beds into a very solid body," Mr Oldacre remarks (in "Horticultural Transactions," vol. ii.), "is a most essential point, for without it you

cannot expect success; and the thickness of these must be particularly attended to, for where there is a much greater body, the beds will be subjected to a strong fermentation, and will be prevented by evaporation from retaining that consistency in the dung which is absolutely necessary for the production of a good and plentiful crop. On the contrary, if a much less quantity be laid together, the heat and fermentation will be insufficient to prepare the beds for the nourishment of the spawn; but the assistance of both, to the extent prescribed, cements the materials together, which, in addition to beating, increases greatly their solidity. The proper vegetation of the spawn, and the consequent crop of mushrooms, depend entirely upon a moderate genial heat and fermentation, neither too strong nor too slight." As soon as the temperature in the beds reaches from 80° to 90° Fahr., "the beds are beaten a second time, to render them more solid, if possible. Then make holes with a dibber 3 inches in diameter, and 9 inches asunder, through the compost in every part of the beds. These holes will be a means of cooling them, and preventing that excess of heat from taking place which would produce rotteness, and render them unproductive. If the beds do not attain the heat required in four or five days after they are put together, add another layer of compost, 2 inches thick, which will probably increase the heat sufficiently; if not, a part of the bed should be taken away, and the remainder mixed with fresh horse-droppings, and wrought together in the same way as before, in order to produce the proper degree of heat. Beds made after this manner readily generate natural spawn in summer, and frequently in the winter months." The materials for beds made upon this principle ought to be tolerably dry before being put together, as dryness and solidity form its leading feature, and is in reality the chief difference between this method and that of Nicol, already alluded to, whose plan, otherwise excellent, is to some extent defective in this respect. In planting the spawn, Oldacre examines the beds three or four days after the holes have been made; and when their sides are found to be dry, and the heat on the decline, it is introduced by being crammed into the holes, either in whole pieces, or into smaller fragments, and the whole bed beaten down, which finishes the operation. Care must, however, be taken that the heat has not declined too much, and also that it be not too strong at the time, as in either case the spawn would suffer alike, although from opposite causes. "About a fortnight after the spawn has been introduced," he remarks, "examine the holes, and if the spawn has suffered any damage from over-heat or too much moisture in the beds, introduce fresh spawn as before. On the contrary, if the spawn be found good, and vegetating freely in the compost, such beds, if required for immediate production, may be covered with mould, agreeable to the rules hereafter laid down; and the beds intended for succession should remain unearthened, in the summer, till three weeks or a month before you wish them to produce—and in the winter, a

month or five weeks. If the spawn be introduced in hot weather, air must be admitted as freely as possible into the house, till the spawn has spread itself through the beds; for if the place be kept too close, the beds will become soft and spongy, and then the crop will be neither abundant nor of good quality." In earthing over his beds, Mr Oldacre recommends rich maiden earth, wherein its turf is well reduced, laid on to the thickness of 2 inches, and beat as solid and level as possible. Care is to be taken that the soil be not too wet, as in that case it might chill the bed and injure the spawn; nor must it be too dry, because, if so, it could not be beaten so solid as is to be desired.

The subsequent management of the beds, according to the German method, is maintaining a temperature within the house of from 50° to 55°, and the exclusion of light. "In watering the beds extreme caution is necessary, as well in the mode of application, as in the temperature of the water, which should be nearly 80° or 90°," and very lightly sprinkled with a syringe or a small watering-pot, otherwise the mushrooms are sure to sustain damage. If cold water be used, and given plentifully at one time, it will not only destroy the existing crop, but the spawn also, and render the beds so treated of no further utility. If the beds have been suffered to become very dry, it is better to give them several light waterings than one heavy supply. In gathering the mushrooms great care should be taken not to disturb the small ones that invariably, with good management, surround the stems of those which are more early matured. The best method is to twist them up very gently in all instances where it can be done; but where it becomes necessary to cut them, great care should be taken to divest the beds of the stems of those that are cut, as they would rot, to the great injury of those that surround them."

The absence of light in the cultivation of the mushroom has been considered by many an almost necessary condition in securing success, and hence beds are made in dark houses, caves, &c.; while those made in the open air are as carefully deprived of light, by coverings of straw or litter, &c., as if they were placed in the dark catacombs of Paris, where abundance of mushrooms are grown for the Parisian markets. These, however, are far inferior in flavour, and we may also add in wholesomeness, to such as are grown in the open air, in our old grassy pastures, fully exposed to both light and air. "The common mushroom," Dr Lindley observes, "unlike many of its kindred, is by no means a lover of shade; so far from it, the best and most beautiful mushrooms are found in exposed fields, where they delight in a rich soil, retentive of a certain portion of moisture, but well drained. The points, then, to secure in their cultivation are circumstances as nearly as possible similar to those which concur in the seasons most favourable to their growth in the natural ground—an even temperature, a well-drained and generous, but not a rank soil, kept moist, but by no means wet; a free access to light; and such an exposure to air as is consis-

tent with the retention of a proper degree of humidity in the soil, and of temperature. The seasons in which mushrooms are most abundant are those in which a warm but showery autumn succeeds a hot summer—a circumstance towards which attention should be paid by those who would experimentally follow out the subject." These remarks have reference to "A New Method of Growing the Mushroom," by Mr John Hawkin—for the construction of whose mushroom-house, *vide* figs. 663, 664, vol. i. In a communication in the "Gardeners' Chronicle" for 1844 (p. 351), Mr Hawkin thus describes his method of culture: "The principal requisites for the successful culture of the mushroom are heat, light, air, and a damp atmosphere. In the first place, with me the dung is collected fresh from the stables, particularly from horses that are fed on dry food, such as corn and hay. It is thrown into a shed to dry, a little before it is made into beds. My boxes (beds) are trellised at the bottom, which allows the heated air to penetrate through the mass of dung easily; a little hay or rough litter is spread over the bottom of the box, in order to prevent the dung from passing through the trellis-work; and every 2 or 3 inches of dung that is added is beaten hard with a wooden mallet, until the layers reach within 1½ inches of the top of the box. As soon as the heat of the dung falls to a proper temperature, I insert large pieces of spawn into the bed, at the distance of about 8 inches apart. I rarely make use of spawn less than twelve months old, and the less that it is broken I find that it produces the better crops. About a week or ten days afterwards, I finish off the beds with green turf, 1½ inches in thickness, making the beds in my boxes in all about 9 inches in depth. I beat down the turf very firmly with the back of a spade in finishing; afterwards I have no further trouble, except in paying attention to the fire, and in admitting fresh air as it may be required. The house is heated by open tanks (*vide* fig. 664, vol. i.) which run through the centre of it, and which return again into the boiler, giving out a sufficient quantity of moisture for the necessary development and growth of the mushroom. During night the grassy turf becomes copiously loaded with moisture; and should the following day prove fine, I never omit giving abundance of fresh air by the doorway. The temperature of the house ranges from 60° to 65° during the day, and at night it is frequently allowed to fall as low as temperate. The great advantage of growing mushrooms upon fresh grassy turf is obvious to any one accustomed to their cultivation." Mr Hawkin, in another respect, deviates even still further from ordinary practice. "I have been," he says, "in the habit of growing mushrooms, and with great success, upon coal refuse for the last two years; and at present I have two boxes at work, one covered with coal-dust, and the other with turf. The produce of these shows the relative advantages of the two methods, for although those from the coal-dust are large and of good flavour, they are decidedly inferior, in both respects, to those produced by the grass-covered beds; indeed, such is the superiority of the latter, that

if the mushrooms from both beds were gathered and mixed indiscriminately, any one could without difficulty select those grown upon the turf from those raised on the beds covered with the small coal." In a later communication Mr Hawkin observes: "In my former paper I did not mention the shape in which the greensward is best adapted for the free spread of the spawn. I have since discovered that the turf is best after being partially dried in a shed, taking care to preserve the vitality of the grass, which I consider very essential in the growth of mushrooms. In all my experience, I have never seen them purely white on the crown, or the gills as red as the finest field mushrooms, and fully equal to the latter in flavour, but by this process." Mr Hawkin concludes by observing that he is confident that light and air, where an equal temperature can be preserved, are essential to the growth of the mushroom, and that they do not blanch by the exclusion of either; if they did this, the gill would also turn white proportionably—a dark confined atmosphere will never produce a healthy full-grown mushroom. One great advantage attends this method—namely, the labour and inconvenience of covering and uncovering the beds are dispensed with. Covering the beds with turf instead of loamy soil is a much nearer approach to their natural condition; besides, it retains the declining heat in the beds better; and should that heat fail, so as to render a top-dressing of dung necessary to increase the temperature, it can be more conveniently effected than if the bed was earthed up in the usual manner.

*To secure abundance of mushrooms during winter* is a matter of great importance to most people. The writer of the forcing department of the calendar of operations in the "Gardeners' Chronicle," 1845, p. 612, has given the following very rational directions: "The best way to secure good and lasting crops of mushrooms through the autumn and up to Christmas, is to make the beds in good time, and to give them plenty of time that they may work slowly, depending more on the warmth of the atmosphere than upon fermentation in the manure. The natural warmth in the last fortnight in August and the first three weeks in September will guarantee the safe working of the spawn, provided a proper medium is procured. Three things are requisite in the dung, to insure success in getting the spawn to work well—viz., what is technically called "sweetness," an open texture, and a medium degree of moisture. It is a good plan to make the beds in the mushroom-house at twice—that is to say, if the shelf be 1 foot in depth, which is not too much for substantial beds, 8 inches might be made at any time in July and August, and the remaining 4 inches as wanted. In this case, get new droppings from the stable-door, with a deal of fresh litter amongst them; and add one-third of strong loam at least, heating the whole into a solid mass. For the surface of such beds, well-fermented dung alone should be used, only made at least two months before the mushrooms are required, giving it plenty of time, without the hurry of fermentation, to establish itself all

through the mass. It should be borne in mind that depth in the bed, and loam mixed with the dung, tend at all times to render the bed more durable. Remember that mushrooms are as fond of abundance of air and light as other plants. They grow most in the fields at night, not because they hate light, but because they can enjoy abundance of atmospheric moisture, which is so quickly dispersed by the returning day. Let, then, abundance of atmospheric moisture be secured at all times, as also an unfavourable temperature of 55° or 60°, and no fear need be entertained of injury from light or air, either day or night."

The practice of growing mushrooms in more light and air than was the practice formerly, is now greatly gaining ground; and as the principle is founded on correct data, we cannot recommend it too strongly to our readers.

Besides producing mushrooms on beds made in the open air, as practised by the London market-gardeners, or in regular mushroom-houses, as is usually done by private gardeners, other means are often had recourse to, such as growing them in boxes, or even large flower-pots, placed in a proper temperature in warm cellars, offices, and spare places in hot-houses. Spawn is also often introduced into melon-pits and frames, as soon as the strong heat of the fermentation in the beds has subsided. The mushroom spawn, when broken into smallish pieces, is laid upon the soil which forms the hills on which the plants are set, and also over the surface of the bed. The earthing up and usual routine are followed, as regards the melon plants, the same as if no spawn was planted. In September or October, when the melon crop is finished, the haulm is removed, the glass lights kept on, and, as little water has been applied during the ripening of the melons, the spawn is in consequence encouraged to run over the whole surface. When this is found to be the case, gentle waterings with tepid water are given, and mushrooms are produced in great abundance. Should the weather become cold, linings of hot dung are applied, which warm the beds, and stimulate the spawn into renewed vigour. No darkened covering is put over the beds; while the spawn continues in a healthy state they receive no other covering than the glass, thus exposing them fully to the light: but if cold weather ensue, the glass is covered during night in the usual way. By this means the Rev. W. Williamson (who has detailed his practice in the 5th vol. of the "Horticultural Society's Transactions," p. 3) informs us he has gathered "2 bushels from a frame 10 feet by 6 feet, at one gathering, some of the mushrooms weighing 2 lb. each. The mould being kept warm by the glasses, and properly watered, the mushrooms will continue to spring till the frost of winter prevents their further growth. I then," he continues, "leave the bed, frame, &c., just as they are; and early in spring, as soon as the frost may be supposed to be over, I take off the frame and glasses, and cover the bed lightly with straw; when the warm enlivening showers of spring cause the mushrooms to be again produced in every part, till the drought of summer

renders it difficult to keep the bed sufficiently moist for their growth. Sometimes I suffer the bed to remain, in order to produce a crop in the second autumn, but more generally take the bed to pieces for the sake of the dung, and also for the purpose of procuring and drying the spawn against the return of spring." Abundant crops of fine mushrooms are often produced by forming a small trench in the open garden, and filling it with the remains of an exhausted mushroom-bed, which is covered to the depth of 2 inches with soil; and on these are planted broccoli, cauliflower, &c. The spawn often runs freely during the months of June, July, and August; and, being sheltered from too much rain by the leaves of the plants, mushrooms are produced throughout the autumn in vast quantities and with little trouble.

The cultivation of the mushroom in stables has long been practised by the Baron Joseph d'Hoogvorst, of Limnal, near Brussels, for whose arrangements see fig. 667, vol. i. The beds are prepared much in the usual way of the droppings of high-fed horses, and beaten down in the boxes. One peculiarity, however, in the Baron's practice, and on which he places great importance, is the introduction of a small proportion of sal-ammoniac into his beds, a practice we have nowhere else seen adopted. The leading principles in successful mushroom culture may be comprised under the following heads: Procure proper material, such as high-fed horse droppings; keep them moderately dry; never allow them to come to a high state of fermentation; keep the beds in an atmospheric temperature of from 55° to 65°, and while the spawn is running, the temperature in the bed should not exceed those limits above from 5° to 7°; plant the spawn when the beds are at a temperature of from 65° to 75°; keep them dry while the spawn is running; cover, when it has sufficiently run, to the depth of 3 inches, with sound loamy soil, beat hard down; water, when the crop is wished to appear, and as may be necessary afterwards, with water at a temperature a few degrees above that of the air in the house; admit abundance of light; moderate ventilation; never cover the beds with hay, straw, or litter; make up the beds in March, June, July, August, and September; apply water as nearly in the form of dew as possible; heavy waterings are injurious.

No doubt many of the edible fungi might be as successfully grown as the common mushroom, if sufficient attention were paid to their habits.

The insects most injurious to the mushroom are slugs, snails, and wood-lice. The presence of the two former pretty clearly indicates that the surface of the bed is rather too damp. They must be captured at night, by examining the beds with a candle. The latter is easily entrapped, as it seeks shelter during the day under pieces of slate, or any other similar thing laid on the floors or bed.

The European names for the mushroom are—Champignon comestible in French; Hampernoclje in Dutch; Essbare blatterschamme in German; Pratajuolo in Italian; Seta in Spanish.

## § 2.—THE MOREL.

The Morel (*Morchella esculenta* Pers.), fig. 97, belongs to the same natural order, class, and order

Fig. 97.

THE MOREL.

in the Linnaean arrangement, as the last; it is a native of Britain, found in wet banks and woods, and in moist pastures; it is pretty abundant some seasons in Dalkeith Park, appearing in April, May, and June. In some parts of Dumfriesshire, as about Langholm, it is also abundant, but by no means a common fungus. It is used for the same purposes as the truffle, and if gathered when dry, may be kept for several months. Its cultivation has not, so far as we are aware of, been attempted; of its capability of submitting to culture we think there can

be little doubt. If the spawn were collected from its natural habitats in June, and planted in beds differently formed, but approximating as nearly as possible to its natural conditions, a proper mode of cultivation would assuredly be in time arrived at. Lightfoot, the author of the first "Flora Scotica," says he reared the morel from seed. The great value of the morel, which is one of the most expensive luxuries furnished by our Italian warehouses, and which is by no means met with in the same abundance as some others of the fungi, deserves to be better known than it is at present. The genus *Morchella* comprises very few species, and they are all good to eat: of these, according to Dr Badham, *M. esculenta* and *M. semilibera* only are indigenous to Britain. The "Hortus Britannicus," however, enumerates three species, viz. *M. esculenta*, *patula*, and *hybrida*; as well as two varieties of the former, *rotunda* and *vulgaris*. Dr Badham remarks, "It is less generally known that this fungus, though by no means so common with us as some others (a circumstance partly attributable to the prevailing ignorance as to when and where to look for it, or even of its being indigenous to Britain); occurs not unfrequently in orchards and woods towards the beginning of summer;" and Persoon remarks that it prefers a chalky or argillaceous soil to one of a sandy nature; and adds that it not unfrequently springs up where charcoal has been burnt, or where cinders have been thrown. It is singular that, while the morel is held in such high estimation in Britain, it is little cared for in the Roman markets; and, as an anomalous case, we may mention, on the authority of Badham, that the common mushroom, *Agaricus campestris*, considered by most people in Britain as the only wholesome fungus, is "almost the only one condemned to be thrown into the Tiber by the inspector of the fungus market: indeed, in such dread is this held in the Papal States, that no one knowingly would touch it."

## § 3.—THE TRUFFLE.

The truffle (*Tuber cibarium*, common truffle, Sibthorp, fig. 98; and *Tuber albidum*, white truffle,

Fig. 98.

THE TRUFFLE.

Cæs.) belongs to the same class and order as the last, and, like it, is exceedingly prized in the higher departments of cookery. They are indigenous to Britain, being found growing subterraneously in the southern parts of England. The supply for the market is obtained from the truffle-hunters, who teach dogs to scent them out, which they do with great sagacity, either pointing to the spot, or scratching the ground over where they are growing, when the truffle-hunter digs them up with a spade, rewarding his companion with a small piece of cheese. The truffle is of very irregular form, inclining to globular, without root or stem. The first-named variety (*Tuber cibarium*) is of a dirty black colour, the second (*Tuber albidum*) inclining to white, and both are very uneven and rough on the surface. Besides these, there are imported *Tuber magnatum*, the Piedmontese truffle, and *Tuber brochii*, from Italy. The following British fungi are often substituted for the true truffle, viz. *Hydrobolites tulasnei*, found in Spyke Park, Wilts, and *Melagonaster broomeianus*, or red truffle, found in the neighbourhood of Bath. The truffle has never been satisfactorily produced artificially in Britain, though Bradley, writing in 1726, speaks of its cultivation as an easy matter. The Prussian gardeners have, however, grown it to some extent, and the Comte de Broch has done the same in Italy. The sort grown by de Broch is the *Tuber magnatum*, or Piedmontese truffle, and his *modus operandi* is as follows: In preparing an artificial soil he employs seven parts of garden-soil, two of well-pulverised clayey soil, and one of oak sawdust, thoroughly incorporated together. He also employs the soil where the truffle grows naturally, and this he trenches to the depth of 2 feet, picking out all the large stones, and adding oak sawdust, if necessary, and about one-tenth powdered shells if the soil is too stiff, for the truffle affects a calcareous soil. In preparing his bed, he selects a situation having a northern exposure, and thoroughly soaks his prepared compost with rain-water. After a day or two, when the bed is in a proper state of moisture, he makes holes 6 inches apart in it, in each of which he plants sound and good truffles, surrounding each with two or three handfuls of oak sawdust, covering the rows with a sufficiency of soil to prevent the truffles from being exposed to too much moisture. In this state the bed is left till the following autumn, keeping it in a state neither too wet nor too dry. The truffles began to appear in October, and continued producing till

January. From the Comte's practice little practical information can be drawn, further than that truffles were planted in a situation and in a medium favourable for the seed which was contained in the planted tubers vegetating at its natural season—a circumstance we think more simply accomplished, and with probably as much success, by the peasant truffle-hunter in our own country, who deposits again in the soil all very small and decaying truffles, unfit for market, in the spot from whence he dug them, or transplants them to situations where none grew before, choosing, however, a similar soil, and in general under shadow of a tree of the same species under which they are usually found. The oak and the beech appear to be the most favourable for the purpose. This would lead us to conclude that the truffle prefers a rather dry locality. Bradley's recommendation is, "that the truffle may be easily cultivated where there are woods or coppices of oak or hazel, and where the soil is not too stiff, or inclining to chalk. The soil where they are most found is a reddish sandy loam; this, then, will be the best for our purpose, especially if it has lain long uncultivated. The soil should remain undisturbed till the months of October, November, or December, which is the proper season for planting, if the weather be open, for then the truffles are to be found in their full ripening; and then, likewise, one may find them in a state of putrefaction, which is the time when the seeds are prepared for vegetation. It is in the last state that we ought to gather truffles for planting, or at least they should be in perfect ripeness." He proceeds to plant as follows: "Open a spot of ground, of a convenient space, and take out the earth about 8 inches deep, and screen it, that it may be as fine as possible; then lay about 2 or 3 inches thick of this fine earth at the bottom of the trench, and upon it lay some of the over-ripe truffles, about a foot and a half distance from one another; and as soon as possible prepare a thin mud, made of the screened earth and water, well stirred and mixed together, and pour it on the truffles till the open ground is quite filled up. By this means, in a few hours, the ground will be as closely settled about the truffles as if it had never been dug or disturbed at all, and you may expect a good crop in due time. You must, however, take care to choose your spots of ground in woods or coppices, or such places as are shaded with trees." As regards information on the culture of the truffle, we are in much the same state as were our forefathers ages ago, when it was gravely recommended to them by some of our earliest authorities, to collect the young mushrooms wherever they were found growing naturally, and, on taking them up, to transplant them on dung-beds in their gardens; or, as others recommended, to take full-grown mushrooms, and break them down in water, and water the beds with the infusion. To succeed in the culture of the morel or truffle, we should assuredly follow the course practised with the common mushroom, namely, secure and increase a supply of seed, preserve it in shape of spawn, and transplant it, in that state, into prepared

beds, as nearly as possible resembling that in which they are found to exist naturally. Succeeding in this, more artificial means might successfully be adopted afterwards.

Little has been written on the cultivation of this valuable fungus in Britain. We believe the only works in English that treat on truffle culture are the translations, by Mr Francis Mascall, of M. Alex. de Bornholz's "Treatise on the Cultivation of Truffles," and that of Von V. F. Fisher, entitled "Instructions in Truffle-hunting." The essence of both will be found in the 13th volume of the "Gardeners' Magazine," p. 389-408, and is well worth the perusal of the English reader. The observations of Bradley, quoted above, will be found in his "Physical Observations on Gardening." No less than eleven treatises on this curious subject have appeared in France and Germany, the best of which is the article *Truffle*, by Drs Lippold and Funke, in "Lexicon of Nature and Art," part 3, and the splendid "History and Monograph of Truffles," by Dr Tulasne, Paris, 1851; and the plans proposed for their cultivation by Von Justi and Bulliard are worth consulting. They all agree that a soil should be chosen for the artificial cultivation of this fungi, as similar as possible to that in which truffles grow naturally; that it should be trenched to the depth of 2 or 3 feet; and that either pieces of the earth in which truffles grow naturally, or single truffles, fully grown, should be planted in it. Dr Klotzsch of Berlin recommends taking such truffles as are over-ripe, and nearly in a state of decomposition, breaking them in pieces, and placing them 2 or 3 inches deep in the soil, "in rather raised flat places," under coppices or underwood, and in a sheltered situation. No one appears to have tried its cultivation in a regular mushroom-house, although it at once presents many of the apparent essentials sought for by these authorities, under the shade of trees, coppices, &c.; and we doubt not if those who live in the localities where they naturally abound were to collect the truffles when beginning to decay, at which time their seeds are fully matured, and to transfer them to a bed of earth composed of material similar to that in which they naturally grow, abundance of truffle-spawn would be secured, and might be multiplied as readily as that of the common mushroom: or why not collect the truffle-spawn, and transfer it to artificial beds, as is often done in the case of the mushroom? The truffle being little known to cultivators generally, the following description by Mascall, in addition to our fig. 98, may enable them to detect it with certainty: "Of a round form, more or less approaching to that of a sphere, or of an egg, or sometimes kidney-shaped (for they assume all these forms), and somewhat rough with protuberances. The colour of the surface is, when it is young, whitish, but in those that are full-grown it is either blackish or a deep black. The colour of the inside is whitish, with dark-blue and white, grey, reddish, light-brown, or dark-brown veins, of the thickness of a horse-hair, which are usually variously entangled, and which form a kind of net-work or mat. Between the veins are numerous cavities, filled with a

great deal of mucilage and small solid grains. These scarcely visible glands were formerly said to be the seeds or germs of the young truffles. The less the inside of the truffle is coloured with dark veins, the more tender and delicious is its flesh. The blackish external rind is hard and very rough, by means of fine fissures, grains, and protuberances, and forms, with its small facets, which are almost hexagonal, an appearance by which it somewhat resembles the fir-apples of the larch. Whilst the truffle is young, its smell resembles that of putrid plants, or of moist vegetable earth. When it first approaches the point of time at which it has attained its full growth, it diffuses an agreeable smell, which is peculiar to it, resembling that of musk, which lasts only a few days: it then becomes stronger, and the nearer the fungus is to its dissolution, which speedily ensues, so much the more unpleasant and urinous is the smell, till at last it is quite disagreeable and putrid. Whilst young, the flesh is watery, and its taste insipid: when fully formed, its firm flesh, which is like the kernel of the almond and the nut, has an extremely aromatic and delicious taste; but as soon as the fungus begins to decay, and worms and putrescence to attack it, its taste is bitter and disagreeable."

Wherever truffles are produced, they are to be found the whole year through, from the beginning of spring till late in autumn, but in the greatest plenty from towards the end of the month of August to the latter end of October. They thrive extremely, like all fungi, in warm moist autumns, and are then most delicious. After warm continuous showers, they are found nearer the surface of the soil, sometimes so high that they form little hemispherical mounds of earth, in which small clefts are produced by the sun's rays. If the soil is loose, and dry weather succeeds, the earth which was raised up falls down, and the truffle is seen half uncovered.

The favourite habitat of truffles is a somewhat moist, light, wood soil, which is defended from the immediate effect of the burning rays of the sun by large oak trees standing at a distance from each other, but is not deprived, by thick bushes, of the free access of the currents of air. Where, in woods, there are places bare of timber trees, and with but few bushes, or covered with pollard wood that does not stand thick, they thrive under an oak, beech, white thorn, and even under a fruit tree, and sometimes attain the weight of from a pound to a pound and a half. This unusual size, however, is only met with in moist warm grounds; here they lie nearer the surface of the soil. The drier the soil is, the deeper they are produced in it, but are usually so much the smaller: to this the vicinity of springs is the sole exception.

Truffles vary very much in size, form, and degree of roughness on the surface. Of all varieties those of a whitish colour are most highly prized, and hence the Piedmontese is the most in esteem. Truffles, being destitute of roots, draw their nourishment from the soil by absorbent vessels which cover their whole surface, and these vessels are in general in the form of small warts; and therefore the soil which surrounds

them should be kept in a uniform degree of moisture, for, if deprived of this, they soon wither away. On the other hand, if subjected to too great a degree of humidity, mould and other parasitic plants establish themselves on the surface of the tubers, and by degrees obstruct the absorbing vessels, causing putrefaction to ensue, and its concomitant attendants, insects, which prey upon the tubers, and ultimately destroy them altogether. The first embryo of the truffle is exceedingly small and tender, as is the case with all fungi; and at that stage it is susceptible of injury, both from excess of drought and moisture. Their form is regulated much by the openness or looseness of the soil around them, and hence the necessity of the preparations by deep-trenching and sifting, as above alluded to. "If the soil is everywhere equally loose, the truffle assumes a globular form; but this is changed if there is on one side a greater opposition than on the other: hence the different forms of the tuber may be explained." As a rule in regard to their artificial cultivation, in connection with the state of the beds, we may, in quoting from the translation of Alex. von Bornholz's treatise, observe, "Where the soil is most moist, whether above or below the truffle, there it will either rise up or sink deeper. The degree of power of attraction of the moisture in the earth to that in the truffle, necessitates such a change of place. In moist summers and in wet winters we find the truffles near the surface, even projecting above it. In dry summers, upon poor dry places in woods, they have often to be dug from a depth of more than half a foot. Here is imposed upon them a greater pressure of superincumbent soil. If the earth is not very light, they cannot be fully developed, and therefore remain small. The largest are, consequently, in general, found not deep under the earth, and in shaded light soil—that is, somewhat moist; they are not, however, so well tasted as those of middling size. Vegetable mould from oak leaves and decayed oak appears to contribute to the production and growth of truffles, as advantageously as the dung of horses does to that of mushrooms. In the one case, a peculiar animal matter produces the effect; in the other, a peculiar vegetable matter. Perhaps the tannin, or some other yet undiscovered product of the oak tree, may be the principal cause. The more of this matter any species of tree contains, with the greater facility are truffles produced in its vicinity, and in greater numbers." In the formation of truffle beds, it would appear that they should be of considerable depth, say from 18 inches to 3 feet; the soil finely sifted, and composed of vegetable mould of oak-tree leaves, decayed oak sawdust, or probably half-decayed tanners' bark, as each contains traces of the tannin principle. Calcareous or ferruginous earth should be also employed; and the temperature, shade, and darkness of an ordinary mushroom-house form the fitting situation. In

regard to soil, Bornholz observes, that the greatest number of truffles, and the finest, are found in a light ferruginous calcareous soil. Such a one must, therefore, also be given to the plantations or beds. The soil is found naturally only in particular situations, for which reason truffles do not grow everywhere. The spawn of truffles appears to be extremely delicate, and almost incapable, at least in its natural state, of being transported to any great distance; but this might be overcome, if those in whose vicinity truffles abound were to collect it and form it into spawn-bricks like that of mushrooms. Bornholz, in his treatise, confines himself entirely to their cultivation in woods and forests; all, therefore, that we can glean from his curious production is the medium suitable to the production and growth of this fungus in little other than a natural state.

From the review of Dr Tulasne's "History and Monograph of Truffles," in the "Gardeners Chronicle," 1852, p. 519, we learn that truffles and allied fungi are widely distributed over the globe. Some extend as far north as Upsal, while others are found to occur in Australia. "The black esculent truffles are by nature gregarious: they are found every year in the same spots. They occur exclusively in calcareous or calcareous and argillaceous soils, both on plains and declivities, and generally on ground more or less shaded by trees, but, as it appears, never on ground planted exclusively with conifers. Much has been written on the cultivation of truffles; but, at present, experiments made in confirmation of published statements have not been attended with success. The only fact which is certain is, that their production can easily be effected in certain calcareous soils, even where they may not have been observed before. The plan consists simply in sowing acorns on the soil, and when the oaks have attained the age of ten or twelve years, truffles begin to appear. The extensive truffle layers of Loudon at Vienna were actually produced in this manner. They consisted a few years since of naked uncultivated plains, where truffles were unknown. The plantations must not be too thick. They are cut down for the first time when they are about twelve years' growth, and then at intervals of from seven to nine years. They continue fertile for about twenty-five or thirty years, when at length scarcely any truffles are produced. From the facility with which the mycelium, or spawn, is developed in specimens which have been brought from a distance, Dr Tulasne conceives that it might not be impossible to transplant the more valuable species into truffle layers where the more common sorts only occur. Their presence appears in general to depend more on the mineralogical character of the soil than on particular temperature, limestone districts being certainly most favourable to their growth."

The European names are—Truffel in German; Tartufo nero in Italian; Truffe in French; and Aardnoot in Dutch.

## CHAPTER XI.

### MISCELLANEOUS VEGETABLES.

#### § 1.—RHUBARB.

*Natural history.*—Rhubarb (*Rheum* Linn.) belongs to the natural order Polygenæ, class Ennandria and order Trigynia in the Linnæan arrangement. There are fourteen species of rhubarb, all of which are cultivated either for culinary or medicinal purposes; none of them are indigenous to Britain. *Rheum raponticum*, a native of Asia, was the earliest introduced species, its date of introduction being 1573. The generic name *Rheum* is derived from *Rha*, the Welga, from its being first brought from the banks of that river. It was well known to the ancient Greeks, who called it Rhabarbarum, from its being brought from the above river. The use of its roots for medical purposes is of the greatest antiquity, and we have authentic accounts of its being so used prior to the birth of Christ, as Dioscorides, who was physician to Antony and Cleopatra, wrote on its qualities, and recommended it for use. Paulus Ægineta, who is said to have been the first who practised as an accoucheur, was also the first to use rhubarb as an opening medicine. The root has long been an important article of commerce, and was formerly brought from China, by Tartary, to Aleppo, Damascus, and Alexandria, and from thence it was sent to Vienna, and long maintained the distinction of Levant and Turkey rhubarb. In the time of Gerard, the leaves were used as a pet-herb, and considered superior to spinach or beet. The London Society of Arts, in 1792 and 1793, awarded a gold medal to Sir W. Ferdicce and Mr Jones for rearing rhubarb from seed; and in 1794 a like reward was adjudged to Mr Hayward for propagating it by offsets instead of seeds, for the purpose of bringing it to perfection in a shorter time.

*Use.*—The leaf-stalks of rhubarb have been long used in many parts of England in tarts and pies; in the manner of apples, they are also stewed alone or with rice, made into jellies and other preserves; and when fully grown, the expressed juice is made into an excellent wine. As an article of commercial importance in the London vegetable markets, it is of very recent date. About 1810 Mr Joseph Myatt of Deptford, long known for his successful culture of this plant, sent his two sons to the borough market with five bunches of rhubarb stalks, of which they

could only sell three. The same cultivator now sends a waggon-load or two twice a-week to the London markets, besides many other growers, who supply the metropolitan markets with many tons of stalks weekly during the season.

*Propagation, &c.*—All the varieties of rhubarb are reared from seed, which is the best way, but very generally they are increased by dividing the roots, retaining a bud or crown to each section. Whether originated from seed or increased by division, a deep rich soil is required to insure the full development of the foot-stalks, for upon their size, rapidity of growth, and consequently tenderness of fibre, much of their merit depends. The soil should be rich and mellow, but not damp, and should be trenched not less than 3 feet in depth. The seed should be sown in March, in drills a foot asunder, thinning the plants out, when a few inches high, to 9 inches apart. In autumn following they will be fit for transplanting in rows 3 feet asunder, and the plants set 3 feet apart. The same distance should be given to sets when propagation is effected by division of the roots. As, however, some of the sorts grow larger than others, a corresponding distance should be accorded them, extending to 5 feet between the rows, and 3 feet plant from plant. When manure is applied, it should be buried not less than from 2 to 3 feet, that the extremities of the roots may derive benefit therefrom. The plants should be set out singly, and not in threes, as is so often done. For the first year the ground between the rows may be cropped with lettuce, turnips, or similar low-growing crops; but after the second year the leaves will cover the whole space, and require it also for their full development. From the depth to which the roots extend, subsequent manurings will have little effect upon them; therefore, in preparing the ground for a new plantation, it should be enriched to the depth recommended above; and if a liberal supply of broken bones be incorporated with the manure, so much the better, as they consume slowly.

The *after culture* consists in keeping the ground clear of weeds, breaking over the flower-stalks as they appear, that their formation and seed-producing may not draw unnecessary supplies from the roots.

*Gathering the crop.*—During the second year

after planting, a few of the largest and first-formed leaves, with their foot-stalks attached, may be gathered for use; but this gathering should not commence too early in the season, because in that case the plants would be weakened. From the third year, as long as the plantation lasts, it may be gathered with freedom. A plantation in a good soil, and not overmuch deprived of its foliage, will last from ten to fifteen years; but the former period is more consistent with good management, because plants under that age will be more vigorous, and this will admit of a rotation taking place in the ground. When the leaves are about half expanded they may be taken off for use; but where the largest returns are expected, as in the case of market-gardens, they should be allowed to attain their full size. In removing them, they should be pulled off close to their base, and not cut, to prevent an unnecessary escape of sap, which in all succulent plants flows more copiously from a clean cut than from one slightly lacerated or torn; the foot-stalks should then be separated from the leaves, and tied up in bundles of from six to twelve in each, in which state they are fit for the kitchen. The London market-gardeners' practice of growing rhubarb is to manure the ground heavily; established plants are taken up and divided into as many pieces as they have eyes or buds; these are planted in March at 4 feet apart, and by autumn they will have produced roots from 6 to 12 lb. in weight. They also, in like manner, cut up the roots that have been taken up and forced during winter, and with them form new plantations in spring.

*Forcing.*—No plant is more easily forced than this, and in consequence it is had fit for use from the beginning of December until it comes into season in the natural ground. The London practice is to dig long pits, in any convenient part of the ground, to the depth of 2 or 3 feet, introducing 18 inches of hot dung. The roots, being taken carefully and entirely up, are set upon this dung closely packed together, having a sufficiency of mould worked in around them, to keep them excluded from the air. These pits are then hooped over and covered with mats, and over that 6 inches of straw. Watted hurdles are also employed to place over them, and over these a covering of straw or dry litter in thickness more or less according to the state of the weather. Mr Cuthill remarks that in wet seasons rhubarb, when forced in the open ground, is deficient in flavour compared to what it is in dry and rather frosty seasons; and that the stalks are full of watery juices, which the roots takes up, and which the leaves cannot throw off or assimilate in consequence of being deprived of light and air, and that in such seasons the leaves often rot off entirely. This has led some market-gardeners to adopt means of keeping the roots dry, and to this end they pack the roots in rather dry mould, and place them on the floors of long sheds, and cover the crowns to the depth of 2 feet with tree leaves. This is a much better method than forcing in the open air; but where such quantities are forced as are produced by the London commercial growers,

an immense extent of shed room would be required. A much better way would be to place the roots upon a slight dung-bed, and to cover the whole with a portable roof constructed of boarding, laid in an imbricated manner, as shown at fig. 52, as used by us for protecting celery. The predilection which the London growers have for coverings of mats and straw has not one merit to recommend it, is sanctioned only by an antiquated and absurd prejudice of long standing, and entails a considerable expense in labour and material, which might be saved by a very limited amount of ingenuity. Forcing in private establishments is in most cases better done. Our own practice is to take up the first set of roots as soon as the leaves have died away, to remove them to the under beds of a mushroom-house, to a warm cellar, or to an apartment behind one of the pine-stoves, as already described under the article SEA-KALE, p. 106; and those who have not these conveniences may set the roots on the floor of an early peach-house or vinery, or even behind the flues or hot-water pipes, covering the roots with soil to exclude air and retain sufficient moisture around them, and to allow the leaves and foot-stalks to develop themselves in all the light such places afford. Some attach importance to growing rhubarb in the dark, with a view to blanch it. This process has no other effect than that of greatly deteriorating the flavour of the crop.

A temperature as low as that recommended for sea-kale, p. 106, and similar treatment in every respect except that of blanching, is all that is required for producing rhubarb in its fullest perfection during the winter season.

*To save seed.*—One flower stem, if left on a single plant, will afford a sufficient quantity for maintaining a succession of young plants. Insects and diseases are unknown to the rhubarb.

*Estimate of sorts.*—The original species of *Rheum undulatum*, *R. palmatum*, *R. Rhaponticum*, &c., have now nearly given place to hybrid varieties, possessing the merits of larger size, delicacy in texture, improvement in colour, or coming earlier into use: of these, the

*Elford* or *Bucks early scarlet* is, although a small-growing sort, esteemed for its brilliant scarlet colour, which it retains although forced in darkness.

*Britannia rhubarb.*—An early variety, and possessing the rather rare merit of scarcely ever throwing up flower-stems. The leaf-stalks grow quite erect, and are both numerous and of large size, and of a beautiful dark pink colour.

*Royal Albert.*—Not so early as the last, nor so productive, on account of the energies of the roots being wasted in the support of the flower-stalks which it so readily sends up, and that in its earliest stage of growth.

*Mitchell's grey eagle.*—A new and excellent variety, originated with Mr Mitchell of Enfield.

*Randall's early prolific.*—Comparatively a new variety, of great merit and productiveness, as yet little known in the provinces; high coloured and well flavoured.

*Myatt's Linneus.*—Of medium earliness, yielding large crops of leaves.

*Myatt's Victoria.*—The latest, with the excep-

tion of *R. Emodi*, a sort seldom grown, and therefore valuable, as prolonging the season of this excellent vegetable.

*Goliath*.—Of medium earliness, and of large size.

The European names for rhubarb are—*Rhubarbar* in French; *Ruibarbo* in Spanish and Portuguese; *Rabarber* in German and Dutch; *Rabarbaro* in Italian.

## § 2.—THE TOMATO AND EGG-PLANT.

The tomato or love-apple (*Lycopersicum esculentum*, Tou, L.) belongs to the natural order Solanæ, section Pericarpum baccatum, and to the class Pentandria and order Monogynia in the Linnæan arrangement. All of the genus *Lycopersicum*, consisting of nine species and several varieties, are cultivated in their native countries (Peru and South America) as esculent fruits. The common tomato (*L. esculentum*) was introduced to Britain in 1596, and with its varieties much cultivated, although, in most of Britain, requiring the protection of glass. The name is derived from *Lykos*, wolf, *Persicon*, a peach—in poetical allusion to the beautiful appearance and deceitful value of the fruit. The ripe fruit is in much request for making tomato sauce, one of the most delicious and wholesome of all sauces, both for meat and fish. Medicinally considered, it is an excellent substitute for calomel, and can be taken when that valuable medicine cannot, and with much less injury to the constitution. The ripe fruit is much used in soups in this country, and in France and Italy to such an extent that, to supply the demand, whole fields of the plants are cultivated. In a green state the fruit is pickled, and when fully ripened, the juice is expressed and kept for winter use in the form of ketchup. In the neighbourhood of London it is grown to a great extent, and finds a ready sale in Covent Garden market during September and October, and fetches a good price. It is singular that some of the enterprising growers for the metropolitan market have not thought of producing a supply throughout the year, as few fruits are more easily ripened. We believe we were the first to exhibit ripe tomatoes in Covent Garden market—not for sale, but to show they could be produced in March and April, and, indeed, throughout the London season. The fruit seldom ripens in Scotland in the open air, unless in a few very favourable situations; nor is there much demand for them, unless in families of the highest order. It ripens in the vicinity of London and in the southern counties in August and September, and keeps in good condition throughout October.

The plants are usually propagated by seed, but will strike freely by cuttings taken off the terminating side-branches; and when their culture is to be extended throughout the year, the latter is the best mode, the plants so originated running less to haulm, and fruiting in greater abundance. They may be continued for several years, if kept in a sufficient temperature; but when grown in the open air they perish annually, and, in fact, are annuals in their own

countries. We have had plants in a constant state of bearing for three years, when grown in a pine-stove. The London practice is to sow the seed in seed-pans, in a genial heat, about the end of March, and, when the plants are about 2 inches high, to prick them off into large 60-sized pots, in light rich soil, and keep them near the glass in a growing state, admitting air on all favourable occasions, till the beginning of May, after which they are exposed more freely to harden them off, to be fit to plant out at the bottom of a south wall by the end of that month. They should, however, not be set too near the roots of the fruit-trees, as they exhaust the ground exceedingly. When first planted out, shelter them for a few days by sticking branches in front of them, to ward off cold winds and scorching sunshine. When fully established, they should be as much exposed as possible, as they require all the light and sunshine that even a London climate affords to ripen them thoroughly. Some form beds of warm dung, covering them with frames and sashes, and treat them the same as late cucumbers; others plant them at the base of sloping banks, covering the surface with slates to attract heat, and train the plants upon them. Some train the plant to a single stem, rubbing off all side shoots as they appear, which induces the flowers to issue from the base of the leaves attached to the main stem. Others train the main stem upwards against a wall or paling, and lay in the side branches in a horizontal direction; and others stop the leading shoot as soon as one or two branches of flowers are formed, and retain them in a very dwarf state, by which means a number of plants may be grown in a small space. Our practice is to forward them in pots placed in pits or hot-houses, shifting into larger pots as they advance in growth, and in May to plant them in pits from which early potatoes and such-like crops are removed, and to train them over the surface of the beds like cucumbers, placing slate under them for attracting a greater degree of solar heat. We also grow them in pots 14 inches in diameter, in very rich soil, arranged in a single row along the back of a pit, and train the shoots to the wall, by which means little space is occupied, so that the principal part of the pit can be used for other crops, such as late cucumbers and melons. For winter supply, we grow them in large pots placed along the front of a pine-stove, and train one leading shoot up under each rafter, as at that time the vines are withdrawn from the house. A cucumber or melon house is the best situation for them during winter, and a few plants will produce an ample supply for a large family. Those planted against walls, in the open air, produce abundant crops, in most places of moderate climate, in most seasons, but do not ripen well. If the fruit, when fully grown, be cut off, taking attached to it a foot or two in length of the stems, and suspended under the roof of a pine-stove or vinery, they will ripen to tolerable perfection.

Only two species are cultivated in Britain, the *L. cerasiforme*, or cherry-shaped, of which there is a red and yellow variety; and these are, for some culinary purposes, particularly for dress-

ing whole, preferred to *L. esculentum* or common tomato, of which there are red-fruited, yellow-fruited, and white-fruited varieties, all of which are of various forms and sizes, according to the culture they are subjected to. It is highly probable that some, if not all the other species, deserve our attention, particularly *L. peruvianum*, which is perennial.

The red spider, fig. 22, and thrip, fig. 21, are exceedingly apt to attack the foliage, when grown in a high temperature, and in too dry an atmosphere; and the *Coccus adonidum*, or mealy pine-bug, infests them under similar circumstances.

One or two fruits, saved when fully ripe, will afford abundance of seed for a large garden. The seed should be washed out of the pulp, and, when thoroughly dried, kept in paper bags for future use. It retains its vegetative properties for two years.

The European names are—Tomate in French; Tomates in Spanish; Appeltjes des liefde in Dutch; Pomo d'oro in Italian; and Liebes apfel in German.

The *Egg-plant* (*Solanum Melongena* Dunal) belongs to the same natural order and class, and order in the artificial system, as the last. The generic name is derived from *Solor*, to comfort—soothes by stupifying; the specific name, according to Forskahl, from *Bydendjan*, its name in Arabic—a name by which it is known in all the gardens in the West Indies, where it is much cultivated. It is a native of Africa, and, indeed, is found all over the tropics, where it is extensively cultivated, and used, both boiled and stewed, in sauces like the tomato. A correspondent in the "Gardeners' Magazine" asserts that the Chinese, on great occasions, cook the fruit, which very much resembles a hen's egg both in colour, shape, and size, while hanging on the plant, and serve up the entire plant to table in a pot. The plant was introduced into Britain in 1597. When fit for use, they part freely from the stalk.

Being an annual, it is reared yearly from seed, sown during March in seed-pans, placed in a temperature of 60° to 65°. When the plants have attained the height of 2 inches, they should be set singly in pots of the large 60-size, and still continued in the same degree of heat. As they advance in growth, repeated shiftings will be required; and when in pots 10 or 12 inches in diameter, they may so remain to perfect their fruit. A rich soil is beneficial, and as they seldom ripen in the open air of this country, they generally are accommodated with a place in a pit or greenhouse, after the plants have been removed out of doors for the summer season. Here they become both ornamental and useful. One fruit will afford sufficient seed for continuing the stock.

The varieties grown are the common or white-fruited, the violet-fruited, and yellow and red fruited: of these the French prefer the violet-fruited, which they call Aubergine, and this sort is as common in the Paris markets as the tomato. Their favourite mode of dressing them is to scoop out the seeds, filling the cavity with sweet herbs, and then frying them whole. In Britain the plant is in general grown for its singular appearance, few people knowing that

they are a wholesome and excellent food. Under the above management the fruit will ripen about the end of August.

The European names are—Molongene in French; Melanzana in Italian; Tollapfel in German and Dutch.

### § 3. THE GOURD AND PUMPKIN.

The gourd and pumpkin (*Cucurbita ovifera* L., and *C. pepo* L.) belong to the natural order Cucurbitaceæ, and to the class Monœcia and order Monadelphia in the Linnæan arrangement. All the varieties of gourds and pumpkins are eatable, as are also the species of the allied genus *Lagenaria* (bottle gourd), which last are natives of India, while the gourds and pumpkins are natives of Astracan, Chili, the Levant, and other Eastern countries; and although all tender annuals with us, most of them perfect their fruit in most seasons, and in most parts of our country. As the fruit of these plants is used in their green or unripe state, we use the term "perfect their fruit," because it attains its useful condition. The bottle gourds and pumpkins have been cultivated in this country since the latter end of the sixteenth century, but the gourds proper are of much more recent date. The pumpkin, *C. pepo*, has long been cultivated in England, where pumpkin-pies are much relished by the peasantry, who store by the fruit in autumn along with crab-apples for winter use. Many of the varieties are much grown on the Continent, and used in soups and stews, as well as boiled and fried. In America they are largely grown, and used not only for the above purposes, but are also put into pies and tarts.

The succade gourd, or vegetable marrow, is that of all others most cultivated in gardens, and is a profitable and wholesome vegetable. It is used for culinary purposes in all stages of its growth, dressed either whole while quite young, or cut into sections as it gets larger.

The *C. melopepo maxima* (the mammoth or large American gourd) is the largest of all the tribe, attaining the weight of from 160 to 200 lb., keeping for several months after it is ripe, and being used as a substitute for carrots and potatoes in soups and broths.

The majority of gourds are grown in this country for ornament; many of them, when trained to poles, are exceedingly curious; others are grown for use, but not to the extent they are either in America or on the continent of Europe.

As all of them are annuals, they are originated from seed, which should be sown in March upon a moderate bottom-heat, using rich soil, and covering the seed, which is large, to the depth of an inch. Where the number of plants required is not great, it is advisable to plant one seed in a large 60-sized pot, and when about 3 inches high to re-pot into a 48-sized pot, which will be sufficient for the plants until they are to be planted out for good—which rarely can be, without protection, before the middle or end of May. The best situation for the vegetable marrow, or such as are to be grown for cooking, is the top of a compost-heap or dunghill, as they

require a full supply of nutriment at their roots; and from the size of their leaves, &c., they not only cover over compost-heaps or dunghills from sight, but also tend to decompose the latter. During summer they require liberal supplies of water, training the shoots to the ground, and reducing all superabundant side branches, and stopping leaders, after a sufficient crop of fruit has set.

The European names for the gourd and pumpkin are—Courge in French; Zucca in Italian; Abobaro in Portuguese; Kurbis in German; Calabaza in Spanish; Kauwoerde in Dutch. The French distinguish the vegetable marrow by the name of Courge a la moelle, and the Germans call it Markige melonenkurbis. The large American gourd the French designate Potiron jaune; and the Germans, Melouenkurbis.

#### § 4.—CAPSICUM.

Capsicum (Cayenne or Guinea pepper) belongs to the natural order Solanææ, and to the class Pentandria and order Monogynia in the Linnæan arrangement. The generic name is derived from *Kapto*, to bite, from its pungent qualities. They are chiefly natives of India, China, Egypt, and the Brazils, and are all cultivated and much used in the countries to which they are indigenous. The capsicum was first introduced into Europe by the Spaniards; and they are known to have been cultivated in Britain so early as the reign of Edward VI. Their varieties are almost without end, differing in size, colour, and form of their fruit. The commoner varieties are extensively grown by the market-gardeners about London, for the supply of the markets and for the Italian warehouses. They are much used in pickles, seasonings, and made dishes, as both the pod or capsule and seeds yield a warm acrid oil, the heat of which being imparted to the stomach is thought to promote digestion and correct the flatulency of vegetable aliments. The seed-pods of *Capsicum frutescens* furnish the Cayenne pepper of the shops. The expressed juice of the fresh pods affords liquid bird-pepper, so much used in soups in most warm climates. Both the green and ripe pods are used as pickles, and also for making Chili vinegar, which is done by simply putting a handful of the pods in a bottle, afterwards filled up with the best vinegar, and stopping it closely up. In a few weeks it is fit for use. Man-dram, so much used in warm countries to provoke a languid appetite, is prepared by gathering the pods while dry of *Capsicum baccatum* or bird-pepper, and mixing them with cucumbers cut into thin slices, with garlic and shallots cut also very small, to which a little lime-juice and Madeira wine are added, and the whole being mashed and mixed with liquid is fit for use. The pods, gathered fresh and eaten before meals, tend greatly to assist digestion.

The general mode of preparing Cayenne pepper is by gathering the pods when ripe. In India they are dried in the sun, but in Britain they should be dried on a slow hot-plate, or in a very moderately-heated oven; they are then

pounded and sifted through a fine sieve, mixed with salt, and, when dried, put into close-corked bottles for the purpose of excluding the air. This article is subject to great adulteration, flour being often mixed with it, and, still worse, red lead, which is much of the same colour, and greatly increases the weight. The better way is to dry the pods in a slow oven, split them open, extracting the seeds, and pounding them down to a fine powder, or passing them through a coffee-mill, sifting the powder through a thin muslin sieve, and pounding down the parts which do not pass through, and sifting again until the whole is reduced to the finest possible state. Place the powder in air-tight glass bottles, but add no salt or other ingredient whatever. What is called Cayenne pepper-pot is prepared in the following manner, and is sold at a high price in the Italian warehouses: "Take the ripe bird-peppers, dry them well in the sun, then put them into an earthen or stone pot, mixing flour between every stratum of pods, and put them into an oven after the baking of bread, that they may be thoroughly dried; after which they must be well cleansed from the flour, and, if any stalks remain adhering to the pods, they should be taken off and the pods reduced to a fine powder: to every ounce of this add a pound of wheat flour, and as much leaven as is sufficient for the quantity intended. After this has been properly mixed and wrought, it should be made into small cakes, and baked in the same manner as common cakes of the same size; then cut them into small parts, and bake them again that they may be as dry and hard as biscuit, which, being powdered and sifted, is to be kept for use."

The annual capsicum and the larger sorts are usually grown for the supply of the markets more on account of their size than of their quality. We grow the capsicum largely for all culinary purposes, but prefer *Capsicum frutescens*, a shrubby perennial sort, producing small but very pungent pods. These we keep in bearing for from two to three years, when they are thrown away, and successional plants reared from seed.

The European names are—Piment in French; Spanischer pfeffer in German; Peberone in Italian.

#### § 5.—ROSEMARY AND LAVENDER.

*Rosemary* (*Rosmarinus officinalis* L.) belongs to the natural order Labiate and tribe Monardeæ, and to the class Diandria and order Monogynia in the Linnæan arrangement. A native of the south of Europe, from whence it was introduced most probably by the monks in the dark ages. It has long been a cultivated plant in our gardens, and employed for the most opposite purposes. The sprigs are used as a garnish for some dishes; they are also by some stuck into roast-beef while roasting, and are supposed to communicate an agreeable flavour to it. They are in some parts presented to the company at funerals as tokens of remembrance, and are afterwards thrown into the grave. A

decoction of the leaves is much used by ladies to wash their hair with, and it is not devoid of medicinal properties. It is often planted on graves by relatives both in England and on the Continent. The name is derived from *Ros*, dew; *Marinus*, of the sea—that is, dew of the sea. It is a half-hardy shrub, requiring to be planted in a dry poor soil, and in a warm sheltered situation. It is readily propagated by cuttings taken when the young wood is half ripened, and placed in a shaded place under a hand-glass. There are three varieties, the common green-leaved, the silver, and the gold striped—the former is the hardiest. It is also reared from seed, which is imported from France.

The European names are—*Rosmarin* in French; *Romaro* in Spanish; *Rosmarino* in Italian; *Rosmarin* in German; *Rosmarinho* in Portuguese; and *Rosmaryn* in Dutch.

*Lavender* (*Lavendula spica* L.) belongs to the natural order Labiate, tribe Nepetææ, and and to the class Didynamia and order Gynnospermia. A native of the south of Europe. A plant of the greatest antiquity. It appears to be the *Nardus stricta* or *Nardus indica* of ancient writers, and by them was held in high esteem. A very interesting account of this plant is given by Phillips in his "History of Cultivated Vegetables," vol. i. p. 298.

The name is derived from *Laso*, to wash; and the plant is recorded in the "Hortus Britannicus" as being introduced in 1568, but it is highly probable it was cultivated in the monastic gardens at a much earlier period. There are two varieties cultivated, the common and the broad-leaved or French: the former is smaller in the spike, but much more aromatic; the latter is, however, the most extensively grown for distillation and other purposes. Alcohol extracts the virtues of the flowers completely, and gives off by distillation all their odorous parts; water acts less completely. According to the "London Dispensatory," "the oil on which its virtues depend is obtained separately in distillation with water, in the proportion of 1 ounce of oil to 60 ounces of the flowers."

Lavender is grown in most gardens, both for distillation and for being dried and placed amongst linen, as well as forming an ingredient in those repositories of perfumes called sweet-pots. The flowers should be left on the spikes and gathered when quite dry, and just before they are fully expanded. When cut with about 6 inches of the stalks, and tied up in small bundles about an inch in thickness, and suspended from the roof of a dry chamber at a temperature of from 60° to 70°, they will dry in twenty-four hours, and be fit for storing by for use. When the flowers fall from the spikes during drying, they should be gathered up and placed in paper bags, and in this state are as fit for use as if they had remained on the spikes. Lavender is grown to a great extent about Micham in Surrey, for the purpose of distillation; and the lavender-water made of home-grown flowers is considered superior to that imported from France.

It is readily propagated by seeds, cuttings, or slips—the former make the best plants. The seed is procured from France. It should be sown in March in poor light soil; and when the plants are about 2 inches in height they should be transplanted to nursery-beds, in which they should remain till the following spring, when they may be planted out for good. Cuttings are struck in the same manner as with all other shrubby hardy plants, and when rooted should be treated as directed above for seedlings. A dry poor soil is the most favourable, and a warm situation fully exposed to the sun the best place for it, as well as for all other highly-aromatic plants.

The European names are—*Lavande* in French; *Eapliego* in Spanish; *Lavendula* in Italian; *Spiklavendel* in German; *Alfazema* in Portuguese; and *Lavendel* in Dutch.

## § 6.—THE HORSE-RADISH.

The horse-radish (*Cochlearia armoracea* L.) belongs to the natural order Crucifere, tribe Alyssineæ, and to the class Tetrodynamia in the Linnæan arrangement. The plant is a native of England, found occasionally in damp watery places. The generic name is derived from *Cochlear*, a spoon, from the spoon-like or concave leaves of several of the genus. Most of the plants of this family, several of which are indigenous to Britain, are wholesome as salad plants, being powerful antiscorbutics, and capable of stimulating the digestive organs. The horse-radish is cultivated in every garden, and is used as a condiment to roast-beef. The root is the part used, and is served at the table either finely scraped down or grated, which latter is the best and most elegant form. It is also used in winter salads and sauces.

Propagation is always effected by planting portions of the roots, which grow readily, and the soil most conducive to it is a deep, rich, light sand or alluvial deposit, free from stones or other obstructions, as the longer, thicker, and straighter the roots are the more they are valued. With the exception of the Jerusalem artichoke, there is scarcely another culinary vegetable of equal importance in which cultivation is in general so greatly neglected as in this. We find it often, like the former, planted in some obscure corner of the garden, where it may have existed for years, and only visited when the proprietor's table is about to be graced with Old England's national dish. The operation of hastily extracting a root or two is too often all that is thought of, and the crop is left to fight its way amongst weeds and litter as best it may. The best directions laid down for improved culture are the papers by Mr Knight and Mr Judd, in the "Transactions of the Horticultural Society." The former, in vol. i. p. 207, says, "During winter, trench the ground 3 feet deep, and in the following February procure the sets, in the choice of which take the strongest crowns or leading buds from old plants, cutting them about 2 inches long. Mark out the ground in 4-foot beds and 1-foot alleys;

then take from the first bed 9 inches of the top soil, laying it upon the adjoining bed; after which take out an opening at one end of the bed, in the common way of trenching, 15 inches deep from the present surface; then level the bottom, upon which plant a row of sets across the beds at 9 inches apart each way, with their crowns upright; afterwards dig the next trench the same width and depth, turning the earth into the first trench over the row of sets, thus proceeding, trench after trench, to the end. Where more than the produce of one bed is required for the supply of the family for twelve months, the third bed is next to be planted, which treat as directed for the first, only observing to lay the earth on the fourth, and so on for any number of beds. Upon every alternate bed which is not planted a dwarf annual crop may be grown. The plants must be kept clear of weeds during summer, and as soon as the leaves decay in autumn let them be carefully raked off; in the following February 18 inches of the earth of the unplanted bed must be laid as light as possible, and equally over the beds that are planted, then trench and plant the vacant beds exactly in the same manner as before directed. The following autumn the first planted horse-radish may be taken up by opening a trench at one end of the bed to the bottom of the roots, so that the sticks or roots of the crop may be taken up entire, which for size and quality will be such as have not generally been seen. The following February the one-year-old crop will require additional earth as before directed, which must, of course, be taken from those beds which are now vacant." Mr Judd, as described in the work last quoted, takes about 3 inches of the top part of the roots of the crop to be taken up, and those he cuts off, so as to leave only about a quarter of an inch under the crown. He trenches the ground 2 feet deep, and if he applies manure, puts it at the very bottom of the trench. "For if not done," he says, "the horse-radish, which always puts out side roots, would send out such large side roots from the main root, in search of the dung lying contiguous, as materially to injure the crop. In planting, holes are made 18 inches apart every way, and 16 or 18 inches deep. The root-cuttings are let down to the bottom of the holes, which are afterwards filled with

finely-sifted coal-ashes, and the surface of the bed is raked over." We trench our ground for this crop 3 feet deep, laying on a good coat of manure in the bottom, which is well mixed with the soil 2 feet below the surface; the plant-sets, as recommended by Knight above, deprived of all their lateral small fibres, are dropped in holes made by a 2½-inch dibble, gauged to penetrate to the required depth; the holes are filled with the soil above, and the roots left to find their way to the surface, which they do in due season. We have also planted the roots in single lines in trenches dug out as for celery, and as the plants shot upwards, earthed them up during the first season. The winter following we remove all the soil from them, and cut off every fibre from the main stem or root, and earth them up again, by which means we have roots fit for use of a large size and uniform shape. In November we take up as much of the crop as is likely to be used during winter, and pack it by in moderately dry sand in the root-cellar, where it is easily got at when required.

The *Scopula forficularis*, the garden pebble-moth, is the only insect we know of that is injurious to the horse-radish. This insect, in its perfect state, measures rather more than an inch across the wings when fully expanded. The uppermost pair are hazel-coloured, with four stripes, two of which are very distinct, while the other two are faintly traced. The body and under wings are whitish, and on the latter near the middle there is a curved brownish streak, and another of a blackish colour on the margin. The first brood of caterpillars make their appearance in May, while the second do not appear until autumn. They are from 8 to 10 lines in length; head of a light-brown colour; body yellowish-green, with longitudinal black stripes. The means chiefly employed for their destruction are, dusting the plants with white hellebore powder in a dry state; or caustic lime applied in their earliest state is equally effectual. A species of mildew often appears on the foliage, but, so far as we know, has little effect upon them. This is *Erysiphe leguminosarum* Link.

The European names are—Cramson, or Le grand raifort, in French; Ramolaccio in Italian; Rabano in Spanish; Merrettig in German; Looelkraut in Dutch.

## CHAPTER XII.

### SOILS.

#### § 1.—THEIR ORIGIN AND NOMENCLATURE.

AN intimate knowledge of the nature, and even the nomenclature of soils, is of the utmost importance in every branch of cultural science,—to the horticulturist even more so than to the agriculturist, because the subjects under his care are more delicate, and of a much more varied character. The hardier fruit-trees will flourish in soils where the peach, apricot, and vine would refuse to live; and the same rule holds good amongst many of the productions of the culinary garden. It is, however, in connection with the thousands of plants of exotic origin that the nicest distinctions in regard to the nature and nomenclature of soils are called forth; for certain genera of plants—nay, even certain species of the same genus—require a very opposite soil from those brought from the same locality, ranking in the same natural order, and to all external appearances differing little from them. Those which naturally inhabit a silicious soil will seldom exist long in an argillaceous one; and those from peaty soils will not long live in calcareous ones. Seeds of most plants will germinate in a soil composed chiefly of vegetable matter; but after germination, those whose natural food is derived from an argillaceous soil, will soon linger and die of starvation.

There is no universal soil, wherein all the productions of a garden can be grown; while a rich loamy soil may be considered all that is desired by the agriculturist, for in such all his crops will flourish alike. The horticulturist has yearly to collect, from wherever they can be procured, soils of very opposite characters. To him, therefore, a knowledge of the nature of soils is of paramount importance; and that knowledge is only to be obtained by one or other of the three tests—which will be afterwards noticed—namely, botanical, chemical, or mechanical.

Some acquaintance with the nomenclature of soils is to him of equal importance. He may receive plants or seeds from Caffraria, described as having been growing in a silicious soil; from New Zealand, as having been produced in an argillaceous soil; from Canada, in a peaty soil; from somewhere else, in a calcareous

one, and so on. Therefore, without a sufficient knowledge of the difference between these, he would be liable to commit an error of almost daily occurrence, by sowing or planting in a soil perfectly unsuitable for the healthy development of the seed or plant.

A complete nomenclature of soils is still a desideratum, as was the case in every other department of natural science, until the various specimens in each were reduced to systematic arrangement. At present, the names of soils are scarcely even conventional, nor can it be otherwise until they are subjected to the rules of classification; and no doubt they will, through the agency of chemistry, be yet arranged into classes, orders, genera, and possibly species and varieties. The only feasible attempt we know of being made in this very important matter is that of M. de Gasparin, which, although far from perfect, is still a step in the right direction. He divides all soils into two classes—namely, inorganic and organic—and this will, we believe, always be recognised as the fundamental principle of all classification. His subdivisions we do not, however, think sufficiently clear to be of much practical use in their present state. The inquiring reader will find a translation of his arrangement, from the *Comptes Rendues de l'Académie des Sciences*, in the 27th volume of *Jameson's Edinburgh New Philosophical Journal*.

For every practical purpose of cultivation, at least with our present limited knowledge of the subject, soils may be divided into six different classes, and these, we think, will be found to express, sufficiently clear, an idea of the particular soil that is meant.

These are, argillaceous or clayey, containing above 50 per cent of clay; silicious or sandy, containing not more than 10 per cent of clay; calcareous or limey, containing more than 20 per cent of carbonate of lime; loamy, having from 20 to 50 per cent of clay; gravelly, composed of small stones, silica, a small portion of loam or of clay, and often a considerable percentage of oxide of iron, particularly in some pit gravels valued for their binding nature, and employed for walk-making, (in alluvial and river gravel this oxide is much less abundant); peaty, chiefly formed of vegetable matter, in which a large proportion is in an inert state—most so when it exists in deep masses, surcharged with

water, and least so when in a thin surface stratum, resting on a dry base. Before, however, treating on these individually, we may offer a few brief remarks on the origin of soils generally.

"It is the generally received opinion of the formation of soils, that they have proceeded from the detrition of rocks by the force of external agencies; that the disintegrated materials have been carried by floods to the ocean, and, there accumulating, are formed into horizontal layers. But the decay of rocks themselves must be very gradual: in some dry countries, inscriptions are perfect, and their angular edges and shapes but little blunted or altered, after a lapse of twenty centuries. The formations that are taking place, in the present quiescent state of the globe, are made by the sea, fresh-water rivers, and by lacustrine deposits from substances collected and rolled along by the course of the waters over the earth. The depositions go on in many places visibly, though slowly: but we know little of the processes by which the vast alluvial deposits have been made, in all the different arrangements, mixtures, and combinations, to the depth of several hundred feet, and extending over vast tracts of various and discordant qualities; or of the means employed by nature in the process of alluvial deposition from the detritus accumulated at the foot of mountains, from the decomposition of rocks, and of the subsequent removal and consolidation, or even of the operations by which animal and vegetable exuvies are converted into soil. But these petrifications and organic remains would seem sufficient to place one fact beyond dispute, that the globe has undergone many extensive changes; and it is not a little curious that they are confined to particular formations, and are not found in contiguous strata, and that the remains of trees and vegetables are found only in some few similar situations. Soils are often found to contain substances that do not exist in the rocks on which they rest; and rocks frequently possess materials of which no vestiges can be detected in the upper soil, and which, being destructible, would be found in some degree or quantity, if soils were derived from the adjacent formations. These circumstances would appear to indicate that other agents than detrition have been at work in the production and creation of soils.

"The alluvial formation constitutes the greater mass of the surface of the earth, and is composed of rocky substances, formed of previously existing rocks, and supposed to be formed by the detrition and ruins of other formations, broken down by the gradual action of water. They are loose in texture, and are never covered with any rock or solid secondary strata, and may be reckoned a very recent deposition, the formation of which is still going on. The deposit is mostly composed of clay, sand, and gravel, which, in a great variety of combinations and modifications, constitute what is termed land or soil. They contain sands from quartz, and clays from the disintegration of slates, felspar, and micaceous rocks, mixed with other substances, and fill up hollow places, and

form very extensive tracts. They also contain calcareous tuffs, common salt, and peat, subterranean and submarine forests, bogs, iron ore, metals, ores, and gems in grains."—DONALDSON on *Soils and Manures*, p. 10.

This view appears also to have been taken by Mr Morton, who observes in his work on soils, that "the surface of the earth partakes of the nature and colour of the subsoil or rock on which it rests. The principal mineral of the soil of any district is that of the geological formation under it. Hence we find argillaceous soil resting on the various clay formations, calcareous soil over the chalk, and oolitic rocks and silicious soils over the various sandstones. On the chalk the soil is white; on the red sandstone it is red; and on the sands and clays, the surface has nearly the same shade of colour as the subsoil. The lime, potash, and iron, existing in various proportions in the rock, are acted upon by the atmosphere, and the rock is decomposed; some of it will form impalpable matter, some into sand, and some into coarse gravel or rubble. The surface is composed of the same materials as the subsoil, with the addition of vegetable and animal matter, in every state of decay, internally mixed with it; and we perceive a change in the external appearance of the surface whenever there is a change in the subsoil below."

Whitley, in "Application of Geology to Agriculture," dissents somewhat from these opinions, and asserts that "the ordinary effect of atmospheric influence does not appear sufficient to produce such changes. We are therefore led," he continues, "to the conclusion that some more powerful and effective agent has been at work; and the phenomena connected with the facts we have reviewed are only consistent with the theory of a vast body of water having, by its violent action, broken and comminuted the earth's surface to a considerable depth, thus holding in mechanical suspension the materials of which the soil and subsoil are composed—the coarser and heavier parts first subsiding, then the clays, and lastly the fine earthy matter. In endeavouring to establish this view of the formation of soil, the decomposition of rocks by atmospheric and chemical agencies must not be overlooked. These causes had probably produced extensive changes before that catastrophe, whose effects we have just been describing, and to the present time their operation tends to improve and deepen the soil. The crumbling down of rocks by decomposition may be regarded as conservative of the soil, by supplying fresh portions to replace those that are constantly washed away." Notwithstanding the attempt to establish this water theory, which is by no means new, Mr Whitley cannot altogether get rid of the theory laid down by Donaldson, Morton, and others. Ansted, in "Geology," vol. ii., follows, although in a more modified degree, the views of Whitley stated above.

In reviewing these opinions, Mr Henry Stephens, in "The Book of the Farm," we think very justly, draws the following conclusion: "It appears to me the origin of the soil is not to

easily explained as the matter seems to be assumed by the authors just quoted; and that difficulty attends the explanation of their origin may be inferred from the fact of most geologists having hitherto paid little attention to the relations of the loose materials composing the surface of the globe. They are well acquainted, and coincide in opinion, with the relations of the indurated rocks which form the crust of the earth, but are far from being agreed as to the causes which have placed the enormous masses of incoherent matter, met with in every quarter of the globe, in their present positions. These masses of clay, sand, and gravel, bear no fixed relation to one another, like the indurated rocks, and, therefore, have not been placed by the operation of any law of order, but simply that of gravity; and it is this want of order in their position which baffles the ability of the geologist to ascribe the origin correctly."

The highly respectable authority last quoted further remarks: "Notwithstanding the possibility of the formation of mould upon the surface of hard rocks by means of atmospheric influences, there cannot, I think, a doubt exist that by far the largest proportion of the agricultural soil is based upon the incoherent, and not on the indurated rocks." The term rock, it should be observed, is used here as applied by geologists, "not only to the hard substance to which this name is commonly given, but also to those various sands, gravels, shales, marls, or clays which form beds, strata, or masses;" and the conclusion arrived at by Mr Stephens is, "that the agricultural soils of the low part of a country are generally not derived from the hard rocks upon which they may happen to be placed, but have been brought to their present position from a distance by means of water." After stating various cases which have come under his own observation, he proceeds: "It is not denied that the chemical action of the air, and the physical force of rain, frost, and wind, produce visible effects upon the most indurated rocks; but of course they must have much greater effects upon incoherent ones. Combined in their action, they could only originate a mere coating of soil over the surface of indurated rock, if the rock were situated within the region of phanogamous vegetation, because it would then be constantly covered with plants. But the plants in their turn would protect the rocks against the action of external agencies; and although they could not entirely prevent, they would at least retard the accumulation of soil beyond what the supply of vegetation required. Some other agent, therefore, more powerful than the ordinary atmospheric elements, must be brought to bear on indurated rocks, before a satisfactory solution of the formation of soils can be accepted. That other agent is water; but the moment we assent to the agency of water being able, by its abrasive power and buoyant property, when in motion, to transport the abraded parts of rocks to a distance, and let them fall in coming in contact with some opposing barrier, that moment we must abandon the idea of the soils formed from abraded matter being derived from the indurated rock upon which they rest. Mr Buist draws these

conclusions, after describing the relative positions of deposits to the rocks upon which they rest, in a large and important district of Perthshire, where he says "that the alluvial matters of these districts, in general, belong to periods much more remote than those originally assigned to them, and came into existence under circumstances prodigiously different from those which presently obtain; that the present causes—that is, the action of our modern rivers, brooks, and torrents, and of the air and water on the surface now exposed to them—have had but little share in modifying our alluvial formations, or bringing them into their present form." Professor Johnston, in "Lectures on Agricultural Chemistry and Geology," sums up this matter in the following words: "Thus the general conclusion is fairly drawn, that the earthy matter of all soils has been produced by the gradual decay, degradation, or crumbling down of previously existing rocks. It is evident, therefore, that whenever a soil rests immediately upon the rock from which it has been derived, it may be expected to partake more or less of the composition and character of that rock; and that where the soil forms only the surface-layer of a considerable depth of transported materials, it may have no relation whatever, either in mineralogical character or in chemical constitution, to the immediately subjacent rocks. The soils of Great Britain are divisible into two such classes. In some countries an acquaintance with the prevailing rock of the district enables us to predict the general character and quality of the soil; in others—and nearly all our coal-fields are in this case—the general character and capabilities of the soil have no relation whatever to the rocks on which the loose materials immediately rest."

Sir H. Davy, in accounting for the transition from rock to soil, remarks that the operation may be easily conceived by referring to the instance of soft granite, or porcelain granite. This substance consists of three ingredients—quartz, feldspar, and mica. The quartz is almost pure silicious earth in a crystalline form; the feldspar and mica are very compounded substances: both contain silica, alumina, and oxide of iron. In the feldspar there is usually lime and potash; in the mica, lime and magnesia. When a granite rock of this kind has been long exposed to the influence of air and water, the lime and potash contained in its constituent parts are acted upon by water or carbonic acid; and the oxide of iron, which is almost always in its least oxidised state, tends to combine with more oxygen. The consequence is, that the feldspar decomposes, and likewise the mica, but the first the most rapidly. The feldspar, which is, as it were, the cement of the stone, forms a fine clay; the mica, partially decomposed, mixes with it as sand; and the undecomposed quartz appears as gravel, or sand of different degrees of fineness. As soon as the smallest layer of earth is formed on the surface of a rock, the seeds of lichens, mosses, and other imperfect vegetables which are constantly floating in the atmosphere, and which have made it their resting-place, begin to vegetate. Their death, decomposition, and decay afford a certain quantity of organisable matter, which mixes

with the earthy materials of the rock. In this improved soil more perfect plants are capable of subsisting; these in their turn absorb nourishment from water and the atmosphere, and, after perishing, afford new materials to those already provided. The decomposition of the rock still continues; and at length, by such slow but gradual processes, a soil is formed on which even forest trees can fix their roots, and which is fitted to reward the labours of the cultivator. Such, therefore, being the opinions offered regarding the primary formation of soils, let us briefly consider them in the order in which they stand above.

*Argillaceous or clayey soils* derive their name from, and are formed of substances, the basis of which is argil or alumen, alumina or alumine, the oxide of aluminum, one of the newly discovered terigenous metals, which unites with only one proportion of oxygen, and forms the well-known base called alumina, which contains, in one hundred parts of "aluminum," about eight of oxygen. Sir H. Davy laid it down as a rule in practice, that the name clayey soil should not be applied to any soil unless it contained one-sixth of impalpable earthy matter, and did not effervesce to any great extent with acids. Argillaceous soils occur in extensive and often very thick beds in most alluvial districts, transported thither by the agency of water, and accumulating for ages. This soil is much mixed with silica and other matters, and is found of different colours, as oxide of iron in different states and combination is amalgamated with it. Clay enters into all good soils; in fertile ones it abounds to the extent of 9 to 15 per cent, whilst in barren lands it exists to from 20 to 40 per cent. "The absence of it," Donaldson observes, "forms a soil too dry and porous: a proper quantity forms the best clay lands and clayey loams, and a superabundance of it constitutes a soil too wet and cold for vegetable life, in a moist state, and hardening and contracting by heat into a state very hurtful to the growth of plants. The purest clay contains upwards of 60 per cent of sand, and is always mixed with mineral, animal, and vegetable substances." Stiff or strong clays, although they absorb the greatest quantity of water when it is poured upon them, or in the case of heavy rains, do not absorb most moisture from the atmosphere in dry weather. They then become caked on the surface, and evaporation from below is consequently interrupted, so that crops are burnt up on them sooner than on light porous sandy soils. Clayey soils are also much colder than lighter soils, because, from their closeness of texture and often superabundance of moisture, the rays of heat are prevented from penetrating them. They are, however, more uniform in temperature, as the same cause that prevents the absorption of heat prevents its radiation also. Clay has a strong affinity for water, on account of the alumina forming its basis retaining it with great tenacity; and it is this quality which constitutes its distinguishing characteristic. "It may be remarked," says Donaldson, "that this quality seems to exist in soils in a smaller proportion than is generally supposed, owing to the state of combination and exposure.

Clay soils of all colours and qualities are known by the property of holding water very tenaciously; and when once wetted, they are dried with very great difficulty. The most general colours of clayey soils are red and black, of various degrees of fertility and texture. The red soils are hardest; the black is softer, and in many cases very waxy and plastic, arising from the minuteness of the particles affording so many points of adhesion. In dry weather they are hard and lumpy, as the red-coloured; in moist weather they dissolve more easily and readily. Clay soils require much power and labour, and dry weather if possible, during the process of being wrought, and narrow ridging or thorough draining in order to carry away the excess of moisture. Clay soils, when well enriched with manures, are naturally well qualified for carrying good crops; but they require much care and industry, as well as a very considerable portion of practical skill in their management, in order to keep them in good condition; yet, when the natural adhesive toughness can be mastered, they generally yield the heaviest and most abundant crops. One grand requisite is, to keep the land in condition; a poor worm-out clay being the most ungrateful of all soils, and hardly capable of repaying seed and labour." Clay soils, although, when in a high state of cultivation, capable of producing, during summer and autumn, most culinary vegetables in a high state of perfection, are very unfit for preserving them through the winter, or for producing them early in the season. If ameliorated by culture, and free from extra moisture, they are well adapted for most of the hardier sorts of fruit trees. The oldest specimens of these with which we are acquainted are growing in rich alluvial clayey soils.

The composition of pure clay is thus given by Donaldson, p. 15:—

Silica, . . . . .	0.35
Alumina, . . . . .	32.5
Lime, . . . . .	0.35
Oxide of iron, . . . . .	0.45
Sulphuric acid, . . . . .	19.35
Water, . . . . .	47.00
	100.00

*Silicious or sandy soils.*—This term can only with strict propriety be applied to soils having at least seven-eighths of sand in their composition, and which do not effervesce when acids are applied. Calcareous sandy soils, which may be considered a variety of this soil, are readily distinguished from the strictly silicious by efferevescing when acid tests are employed. "Sandy soils are composed of the rough, dry, and hard granulations of stones that have been disintegrated and reduced to particles by the action of the various agencies that are supposed to have contributed to the formation of the different substances that are found in the composition of the globe. Sands are much mixed with other substances, and accordingly vary very much in colour: white, red, yellow, brown, black, and green, with many varieties, as the chief colouring qualities are wanting or abundant. When more unequally reduced, sand forms gravel; when composed mostly of flints, it is called silicious; with mica it is micaceous; and when

very finely reduced, it constitutes dust and quicksand. Silica is a most abundant earth, forming a great proportion of primitive rocks, and of the bases of the globe. In fertile sorts it averages 50 to 80 per cent; in barren lands, 40 to 70; but these proportions never mark with much precision the quality of the soil, as so very much depends on mixture and combination in a geographical position. Silica absorbs 0.25, or one-fourth of its weight of water, without dropping, and evaporates twice as fast as chalk, and three times faster than alumen."—DONALDSON on *Soils and Manures*.

Silica forms the chief constituent in most soils, frequently forming nearly nine-tenths of its whole weight; "but this is by no means always the case, for in calcareous or limestone countries we frequently find soils containing a very large quantity of lime. These differences in the proportion of the earthy components of the soil give rise to the varieties of light or free, and stiff or clayey soils, which are also modified by a greater or less quantity of organic substances."—SOLLY'S *Rural Chemistry*.

Silicious or sandy soils absorb heat from the sun readily, and hence are valuable for the production of early crops. They are also wrought with much greater ease, and at almost all seasons with equal propriety. They are incapable, however, of yielding the greatest weight of produce; and fruit trees neither live so long in them, nor are so exempt from various diseases. In homely phraseology, they are considered "hungry soils," and speedily decompose manure when applied to them. This is owing to their want of cohesion and incapability of retaining moisture. Air and moisture readily enter into them, and hence the putrefaction of organic matter goes on rapidly in them, and from want of body to retain its parts, it is soon washed down beyond the range of most roots, or its gaseous parts escape into the atmosphere. In the application of manures, therefore, to such a soil, no more should be applied at once than is sufficient for the sustenance of the crop of the current year. Increasing the depth by trenching will, to a certain extent, correct the former of these defects; and adding argillaceous matter to them in due proportions will transform them into a soil nearly approaching in texture and value to the alluvial.

*Calcareous or limy soils*.—These readily effervesce upon the application of acids, as both lime and magnesia have a powerful affinity for acids, and, in fact, are never present in the soil unless in combination with some of them, and that is most commonly the carbonic. Lime is also not unfrequently found combined with sulphuric acid, constituting gypsum or sulphate of lime. Calcareous soils are confined to the limestone and chalk formations; and in the latter case, when mixed with clay, become exceedingly difficult to work. Such soils, also, are late, and unfavourable for the braiding of seeds. However paradoxical it may appear, there are not unfrequent instances in the chalk countries where, although the substratum may be solid chalk to the depth of a hundred feet or more, there may be a great deficiency of it near

the surface; and hence it is frequently brought up, by sinking shafts and tunnelling, for the purpose of being laid on as a top-dressing, and to make up what is found to be wanting in the surface-soil. Fruit trees do not long exist in a healthy condition where chalk forms the sub-soil. In such a soil, according to Professor Johnston, there are 56 lb. of lime in 1000 lb. of calcareous soil; while barren soil contains only 4 lb. That is, if a soil contains more than 20 per cent of carbonate of lime, it is called a calcareous soil; if it contains no more than 5 per cent, it is called a marly soil.

*Loamy soils*.—This term should be limited to soils containing at least one-third of impalpable earthy matter, and effervescing copiously with acids. Considerable discrepancy, however, appears to exist in regard to what loam really is. "Loam or mould is composed of decomposed animal and vegetable matters, is a principal material in soils, and differs greatly according to the quantity and quality of the matter itself, the state of reduction it has reached, and from the manner in which it is incorporated with the constituents of the soil. Such soils are almost invariably dry, and possess the happy medium of absorbing, retaining, and giving off moisture in the quantity most suitable to the growth of plants. Much of their fertility may be ascribed to the quality of the original subjacent formation being favourable to the growth of vegetation which grew and died upon it, and, along with animal remains, produced the quality and depth of the stratum. The property of depth generally bears a direct ratio to the fertility of the soil, or rather the latter to the former."—DONALDSON on *Soils and Manures*.

Sir H. Davy defines loam as "the impalpable part of the soil which is usually called *clay loam*;" and Reid, in "Chemistry of Nature," offers the following definition: "The term loam is applied to soils which consist of about one-third of finely-divided earthy matter, containing much carbonate of lime." Mr Stephens, in "The Book of the Farm," says—"Loam, in my opinion, consists of any kind of earth containing a sensible admixture of decomposed vegetable matter. I say," he remarks, "a sensible admixture, since no soil under cultivation, whether composed chiefly of clay or of sand, but what contains some decomposed vegetable matter. Unless, therefore, the decomposed vegetable matter of the soil so preponderates as to greatly modify the usual properties of the constituent earths, the soil cannot, in truth, be called by any other name than a clayey or sandy soil; but when it does so prevail, a *clay loam* or a *sandy loam* is formed. But if loam is almost synonymous with clay, then a sandy loam must be a contradiction of terms. Again, a soil of purely vegetable origin—such as crude peat or leaf mould—cannot be called loam, as admixture of an earth of some sort with vegetable matter is required to make loam, under every recorded definition of that term. Thus, then, all soils have the property of clay and sand; and a considerable admixture of decomposed vegetable matter converts them into loam. Hence it is possible for husbandry to convert

any earthy soil into a loam, as is clearly exemplified in the vicinity of large towns."

Loamy soils are by far the most valuable of any, and are also the most numerous. Hence we have clay loams and sandy loams, which are synonymous terms for strong loams and light loams—the former containing a larger proportion of clay, and the latter of sand. Closely allied to these are gravelly loams, which, with sandy loams, are exceedingly valuable, and when unaccompanied with iron are amongst the more useful of all soils. They neither retain too much water, nor do they exclude the sun's heat. They are evidently of alluvial formation, and exist most generally by the margins of rivers, or in the bottoms of valleys. We have also fibrous loams, much sought after by the plant cultivator; as well as virgin or maiden loam, equally in request. The former of these is valued for the abundance of the fibrous roots of plants it contains, which, as they decompose, afford food to the living plant; while the latter is procured from ground that has never been subjected to cultivation; and although a small portion only of organisable matter is found in it, still it is perhaps of all others the best suited to horticultural purposes.

*Gravelly soils* vary considerably in degree—that is, from absolute sand combined with small stones, to gravelly loam. The former and its nearest allies consist almost entirely of small stones and particles of silicious matter, and are barren and unproductive; the latter of fragments of rock or water-worn stones, varying from the size of a large pea to a hazel-nut, or even larger, intermixed with sand and with more or less of loam or vegetable matter. Most of the soils in this section are open and porous, and give off moisture very quickly; and on this account, together with the heat they absorb, are apt to burn in warm dry seasons. Such soils seldom suffer from wet, unless when very shallow and on a retentive subsoil. If unmixed with iron, and containing a sufficient quantity of loam or vegetable matter, gravelly soils are valuable in the garden, yielding early spring crops, and tending, from their dryness, to maintain them during the frosts of winter. They are not, however, in general adapted for fruit trees or fruit-bearing plants. The small stones of which gravelly soils are so much composed tend greatly to increase their temperature, and act as better conductors of heat than the finer particles of sand; but although such soils are more easily heated than sands, they are cooled also in the same proportion. Gravelly soils, when loam and vegetable matter predominate, are, next to light or moderately light loams, amongst the very best garden soils.

*Peaty or mossy soils.*—These are evidently of vegetable origin, and as they contain a superabundance of vegetable matter, often in an inert state, they require the agency of other matter to break them down and fit them for the growth of plants. Peaty soils in any of their modifications are seldom employed in the formation of garden soils, although, in the state of that known amongst plant cultivators as "heath mould" or "sandy peat," they are indispensable

in good culture. Such peat is found, for the most part, on the sides of mountain ranges, and near the tops of secondary hills, and is composed of a basis of black soil, the result of decayed vegetation of the lowest order of plants, intermixed with the remains of heath, *Calluna vulgaris*, &c., and abounding in small white sparkling particles of silica, or fragments of primitive rocks, and sometimes also of small fragments of the more recently formed white sandstone. It is found in shallow beds, seldom many inches deep, evidently the accumulation of ages, partly transported thither by rain and melting snow from a higher altitude, and partly by the decomposition of vegetation. To be useful for plants, this soil must be free of oxide of iron, which often abounds in such formations. Turfy peat is the result of semi-decayed vegetables, various species of *Musci*, *Juncaceæ*, *Cyperaceæ*, &c.; and when dried moderately in the sun and broken down, is valuable for most plants, and may be modified by the addition of sand or loam to suit the majority in cultivation. Black and inert peat is in its natural state totally useless, and can only be rendered useful by burning, charring, roasting, draining, reducing in volume and shape, and by a large admixture of sharp silicious sand. That from the sea-beach is valuable, as carrying with it a considerable amount of saline matter. Peat hogs, which have been drained and cultivated, contain often 80 to 90 per cent of organic matter.

The origin of peat, when in masses, opens up a broad page in the historical changes which a country has undergone. Often under 10 or 15 feet of this substance, and extending over hundreds of acres, may be not only discovered a rich argillaceous soil, but also the marks of former cultivation; in other cases the same soil, in which are still to be found the roots of oaks and other trees, while remains of their trunks and branches are scattered through the superincumbent mass, and these of a size with which our present largest trees are as mere saplings, and, strange to say, often at altitudes where the whole art of man could not get the same species to grow at the present day. Such magazines of almost neglected matter might be advantageously employed by being transported to light sandy or gravelly soils, in which there is a great deficiency of vegetable matter. Their ashes also form valuable stimulants, and assist in the germination of seeds on all, but more especially on strong clayey soils. Celery, potatoes, and carrots are almost the only garden crops that seem to prefer an improved peaty soil. Fruit trees seldom succeed in such, although many shrubs and American trees do.

*Subsoils* exercise a considerable influence on the soil above them. Thus a clay subsoil, being impervious to water, renders the surface soil, of whatever nature it may be, wet and cold. A gravelly or porous subsoil tends greatly to dry, and of course render warmer, the surface soil, even should it be clay; and when a porous soil rests upon a gravelly subsoil, scarcely any degree of humidity can injure it. A rocky subsoil may be either drying or retentive, according to its structure; "a massive subsoil keeping

the soil above it habitually wet ; while a stratified one, if the lines of stratification dip downwards from the soil, will preserve even a retentive soil above it in a comparative dry state." Much, therefore, in the formation of garden soils depends on the subsoil, and to this too little attention has been in general paid. All efforts to improve, or even to make a new garden soil, by the collection of the best materials, will be unsatisfactory, if the subsoil is left impervious to the free passing downward of water, or if left in its natural state, when containing a superabundance of mineral matter unprofitable or deleterious to the roots of trees or plants to be cultivated over it. Where subsoils are retentive of water, they should be thoroughly drained ; where they contain mineral matter unfit for the roots of plants, their character should be changed by the application of counteracting agents.

All soils consist of two parts—*organic* and *inorganic* ; the former chiefly owes its origin to the remains of vegetables and animals, " which," as Professor Johnston observes, " have lived or died in or upon the soil, which have been spread over it by rivers and rains, or which have been applied by the hands of man, for the purpose of increasing its natural fertility. This organic part varies very much in quantity in different soils. In some, as in peaty soils, it forms from 50 to 70 per cent of their whole weight ; and even in rich long-cultivated soils it has been found, in a few rare cases, to amount to as much as 25 per cent. In general, however, it is present in much smaller proportion, even in our best arable lands. The rich alluvial soil of the valley of the Nile contains only 5 per cent of dry organic matter. In stiff and very clayey soils, 10 to 12 per cent is sometimes found ; in very old pasture-lands, and in gardens, vegetable matter occasionally accumulates so as to overload the upper soil. To this organic matter the name of humus has been given by some writers. It contains, or yields to the plant, the ulmic, humic, and other acids. It supplies also, by its decay in contact with the air which penetrates the soil, much carbonic acid, which is supposed to enter the roots, and thus to assist the growth of living vegetables. During the same decay, ammonia is likewise produced, and this in large quantity, if animal matter be present in considerable abundance. Other substances more or less nutritious are also formed from the organic matter in the soil. These enter by the roots, and contribute to nourish the growing plant, though the extent to which it is fed from this source is dependent both upon the abundance with which these substances are supplied, and upon the nature of the plant itself, and of the climate in which it grows.

" Another influence of this organic portion of the soil whether naturally formed in it, or added to it as manure, is not to be neglected. It contains—as all vegetable substances do—a considerable quantity of inorganic, that is, of saline and earthy matter, which is liberated as the organic part decays. Thus living plants derive from the remains of former races, buried

beneath the surface, a portion of that inorganic food which can only be obtained from the soil, and which, if not thus directly supplied, must be sought for by the slow extension of their roots through a greater depth and breadth of the earth in which they grow. The addition of manure to the soil, therefore, places within the easy reach of the roots not only organic, but also inorganic food."

The *inorganic* part of soils is that which remains behind when the organic part is destroyed or abstracted by burning the whole to a red heat in the open air, and consists entirely of earthy and saline substances. The former are insoluble in water, while the latter are soluble. The amount of soluble matter contained in the majority of soils is not great, " and consists of common salt, gypsum, sulphate of soda, sulphate of magnesia, with traces of the chlorides of calcium, magnesium, and potassium ; and of soda, potash, lime, and magnesia, in combination with nitric and phosphoric, and with the humic and other organic acids. It is from these soluble substances that the plants derive the greater portion of the saline ingredients contained in the ash they leave when burned. In hot weather, the evaporation on the surface causes the water to ascend from the porous subsoil ; and as this water always brings with it a quantity of saline matter, which it leaves behind when it rises in vapour, it is evident that the longer the dry weather, and consequent evaporation from the surface, continues, the thicker the incrustations will be, or the greater the accumulations of saline matter on the surface. When rain falls, the saline matter is dissolved, and descends again to the subsoil. In dry weather it re-ascends ; hence the surface-soil of any field will contain a larger proportion of soluble inorganic matter in the middle of a hot dry season, than in one of even ordinary rain : hence also the fine dry weather, which, in early summer, hastens the growth of crops, and later in the season favours their ripening, does so probably, among its other modes of action, by bringing up to the roots, from beneath, a more ready supply of those saline compounds which the crop requires for its healthful growth.

"The earthy or insoluble portion of soils rarely constitutes less than 95 lb. in 100 of the whole weight. It consists chiefly of silica, in the form of sand ; of alumina, mixed or combined with silica, in the form of clay ; and of lime, in the form of carbonate of lime. It is rarely free, however, from 2 or 3 per cent of oxide of iron ; and, where the soil is of a red colour, this oxide is often present in still larger proportion. A trace of magnesia also may be almost always detected, and a minute quantity of phosphate of lime. The principal ingredients, however, of the earthy part of all soils are sand, clay, and lime ; and soils are named or classified according to the quantity of each of these three they may happen to contain."

The following simple rule has been laid down by Mr Johnston, by which the practical cultivator may determine sufficiently accurately the nature of an ordinary soil : " If an ounce of soil be intimately mixed with a pint of water

till it is perfectly softened and diffused through it, and if, after shaking the heavy parts, it be allowed to settle for a few minutes, the sand will subside, while the clay—which is in finer particles, and less heavy—will still remain floating. If the water and fine floating clay be now poured into another vessel, and be allowed to stand till the water has become clear, the sandy part of the soil will be found on the bottom of the first vessel, and the clayey part on that of the second, and they may be dried and weighed separately. If 100 parts of dry soil, not peaty or unusually rich in vegetable matter, leave no more than 10 of clay when treated in this manner, it is called a *sandy soil*; if from 10 to 40, a *sandy loam*; if from 40 to 70, a *loamy soil*; if from 70 to 85, a *clay loam*; from 85 to 95, a strong clay soil; and when no sand is separated at all by this process, it is a pure *agricultural clay*." Such a soil is not of very frequent occurrence; and were it even so, it would be one of the worst for garden purposes.

"If a soil contain more than 5 per cent of carbonate of lime, it is called a *marl*; if more than 20 per cent, it is a calcareous soil. *Peaty soils*, of course, are those in which the vegetable matter predominates very much. The quantity of vegetable or other organic matter is determined by drying the soil *well* upon paper in an oven, until it ceases to lose weight—taking care that the heat is not so great as to char the paper—and then burning in the open air a weighed quantity of the dried soil: the loss by burning is *nearly all* organic matter. In stiff clays this loss will include also a portion of water, which is not wholly driven off from such soils by drying upon paper in the way described. To estimate the lime, a quantity of the soil should be heated in the air till the organic matter is burned away. A weighed portion (200 or 300 grains) should then be diffused through half a pint of cold water, mixed with half a wine-glassful of spirit of salt (muriatic acid), and allowed to stand for a few hours, with occasional stirring. When minute bubbles of gas cease to rise from the soil, the water is poured off, the soil dried, heated to redness as before, and weighed: the loss is nearly all lime."—JOHNSTON'S *Agricultural Chemistry and Geology*, pp. 81, 86.

## § 2.—DETERMINATION OF THEIR NATURE, ETC.

This is only to be arrived at, with any degree of certainty, by botanical, chemical, or mechanical tests—that is, by observing the plants that grow on them; by chemical analysis; and by their roughness, smoothness, taste, smell, or fracture.

For almost all practical purposes the former will be found a safe guide, but for strictly scientific determination a chemical analysis is requisite, while many who are ignorant of both botanical and chemical science arrive at pretty correct conclusions by the last of these. The qualities of a soil may be determined with considerable accuracy, by a good botanist, from the

plants which grow upon it, so far as the actual state of the soil has reference to culture; they do not, however, always indicate the improvement of which it is susceptible, although they do so to a very considerable extent. The *Tus-silago farfara*, or common colt's-foot, is as certain an inhabitant of the blue clay as its existence. It has appeared in the clay brought from the bottom of the London basin when boring for water, and exposed to the air, in places where it existed not before; and the accidental deposit of a single cartload of blue clay upon a barren sandy waste has been soon followed by the appearance of this plant. The *Salicornia herbacea* is only found in saline soils; the *Vaccinium uliginosum* in peaty ones; the *Rumex acetosa* in ferruginous; the *Arenaria rubra* in sandy; and the *Caltha palustris* in marshy soils. Marshy soils are indicated with considerable certainty by the plants which grow in them, and the same may be said of very dry soils; but the earths of fertile soils cannot be inferred with so much certainty, as cultivation, manures, and circumstances have so much changed their primitive character. Chemical analysis is not always to be depended upon either, for testing the soil of a large field for example, as there may be a very considerable difference in various parts of it; so that, in fact, the result of the analysis is that of the identical spot from which the specimen was taken, and may be very different from that of other parts—nay, probably from the greater part of the whole field. Loudon thought that "by far the greater number of plants only indicate the state of a soil relatively to water and organic matter. In short," he observes, "nature may be said to have only three kinds of soil relatively to plants—the dry, the moist, and the fertile." "Such a mode of estimating the comparative properties of soils," says Mr Stephens, "might be correct enough were their products constant; but when these change with the circumstances in which the soil is placed, the test scarcely admits of general application." The very circumstance of changing the condition of soils, whether by adding to or diminishing their natural constituent parts, as by manuring, burning, or draining, no doubt has the effect of causing the disappearance of many plants and the appearance of others; but these latter indicate, by their presence, the change produced, and form a new series of tests by which the soil, in its improved state, is to be again recognised. A copious application of lime will produce plants affecting a calcareous soil, their appearance indicating the addition of a new matter that did not previously exist in it. Draining produces similar results—namely, the disappearance of bog or aquatic plants, and the vegetation of moderately dry soils appearing. High cultivation is productive of a still greater change in vegetable products; for with the manure the seeds of plants are brought in, the produce of more fertile soils—and even with the crops sown—the seeds of plants not even indigenous to our country, although now erroneously considered as such, will be introduced. The *Chrysanthemum segetum* may be offered as an example. Nothing but a complete

change in the constituent parts of a soil will cause the plants of one soil naturally to affect another, a circumstance every plant cultivator knows from experience.

Taking soils in the order in which we have already placed them, we find that in

*Argillaceous soils*, *Saponaria officinalis*, *Orobus tuberosus*, *Lotus major*, *Carex* (many species), *Juncus* (many species), *Tussilago farfara*, *Potentilla reptans*, *P. anserina*, *P. argentea*, *Thalictrum flavum*, *Spiræa ulmaria*, *Aira cæspitosa*, *Equisetum arvense*, &c., exist.

In *Calcareous soils*, *Onobrychis sativa*, *Clematis vitalba*, *Veronica spicata*, *Verbascum lychnitidis*, *Lithospermum officinale*, *Campanula glomerata*, *Phyteuma orbiculare*, *Helianthemum vulgare*, abound.

In *Silicious soils*, *Veronica verna* and most of the annual speedwells, *Silene Anglica*, *Echium vulgare*, *Herniaria glabra* and *H. hirsuta*, *Arenaria rubra*, *Spergula arvensis*, *Papaver argemone*, *P. hybridum*, *Thymus serpyllum*, *Rumex acetosella*, *Acynos vulgaris*, *Tritolium arvense*, *Lamium purpureum*, abound.

*Loamy soils* produce *Anagallis arvensis*, *Sherardia arvensis*, *Valerianella olitoria*, *Lithospermum arvense*, *Lapsana communis*, *Sonchus oleraceus*, *Fumaria officinalis*, *Gnaphalium margaritella*, *Triticum repens*, *Chrysanthemum leucanthemum*.

*Gravelly and peaty*.—In the former chiefly *Polygonum convolvulus*, *P. aviculare*, *Aira caryophyllæ*, *Agrostis vulgaris*, *Lolium perenne*, *Papaver dubium*; and on the latter *Vaccinium* (various species), *Spergula subulata*, *Tormentilla officinalis*, *Calluna vulgaris*, *Erica tetralix*, *Galium aparine*, present themselves.

*Rumex acetosella* indicates the presence of iron, *Equisetum arvense* a cold and retentive subsoil, *Alchemilla aphanes* is indicative of a most unproductive soil; while *Cirsium arvense* and *Senecio Jacobea*, although both affecting light and strong loams, indicate in both cases a fertile one, and the little *Draba verna* and *Scleranthus annuus* are found on the most sterile of all.

This list might be greatly extended, but we have confined it to such plants as are likely to be met with on soils intended for gardening operations. *Stellaria media* and *Fumaria officinalis* are indicative of a rich condition of soil.

*Chemical analysis*.—Most of the authorities we have consulted seem to hold out little hope that the majority of cultivators, in their present state of chemical knowledge, can derive much advantage from attempting to analyse soils themselves, and therefore recommend the employment of professed chemists, who have both the requisite conveniences and a thorough knowledge of the subject, founded on scientific principles.

The quantity of soil best adapted to a perfect analysis is stated to be 400 grains; it should be collected in dry weather, and exposed to the air till it becomes dry to the touch. Discretion must be used in selecting specimens for examination, as soils differ much even within a very limited space. It should therefore be taken from different places, and from 2 to 3 inches

below the surface. It is here that the first and principal difficulty arises in the trus analysis of soils; and if due caution be not exercised, the chemical result may be as far from the truth, as regards the whole field, as if we trusted to its nature from examining the plants which grow upon it. Soils, when collected for this purpose, if not immediately submitted to the chemist, should be kept in close-stopped phials until wanted.

All soils, as may be supposed, are variable in composition: their nature is generally a good deal dependent on the subsoil and the stony matters beneath the surface, many of which are slowly decomposing or crumbling away, and adding to the soil the substances of which they consisted.

We have already stated that a soil, to be useful for the purpose of cultivation, consists of silica, potash, soda, alumina, lime, magnesia, oxide of iron, oxide of manganese, phosphoric acid, sulphuric acid, chlorine, and organic matter. We shall now glance at the relative importance of these constituents to plants, and their amount in the soil, upon the authority of Dr Henry Madden of Brighton, as quoted in "The Book of the Farm."

*Silica*.—This is the pure matter of sand, and also constitutes on an average about 60 per cent of the various clays, so that in a soil it generally amounts to from 75 to 95 per cent. In its uncombined state it has no direct influence upon plants, beyond its mechanical action in supporting the roots, &c.; but as it possesses the property of an acid, it unites with various alkaline matters in the soil, and produces compounds which are required in greater or less quantity by every plant. The chief of these are the *silicates of potash and soda*, by which expression is meant the compounds of silica, or more properly silicic acid, with the alkalis potash and soda.

*Alumina*.—This substance never exists pure in soil. It is the characteristic ingredient of clay, although it exists in that compound to the extent of only 30 or 40 per cent. It exerts no direct chemical influence on vegetation, and is scarcely ever found in the ashes of plants. Its chief value in soil, therefore, is owing to its effects in rendering soil more retentive of moisture. Its amount varies from  $\frac{1}{2}$  per cent to 13 per cent.

*Oxide of iron*.—There are two oxides of iron found in soils—namely, the peroxide and protoxide; one of which, the protoxide, is frequently very injurious to vegetation—indeed, so much so, that  $\frac{1}{2}$  per cent of a soluble salt of this oxide is sufficient to render soil almost barren. The peroxide, however, is often found in small quantities in the ashes of plants. The two oxides together constitute from  $\frac{1}{2}$  to 10 per cent of soil. The blue, yellow, red, and brown colours of soil are more or less dependent upon the presence of iron.

*Oxide of manganese*.—This oxide exists in nearly all soils, and is occasionally found in plants. It does not, however, appear to exert any important influence either mechanically or chemically. Its amount varies from a mere

trace to about 1½ per cent. It assists in giving the black colour to soil."

These four substances constitute by far the greatest bulk of every soil, except the chalky and peaty varieties, but nevertheless, *chemically speaking*, they are of trifling importance to plants, whereas the remaining eight are so absolutely essential that no soil can be cultivated with any success, unless provided with them, either naturally or artificially. And yet, when it is considered that scarcely any of them constitute 1 per cent of the soil, their value will no doubt excite surprise. The sole cause of their utility lies in the fact that they constitute the *ashes of the plants*; and as no plant can by possibility thrive without its inorganic constituents (*its ashes*), hence no soil can be fertile which does not contain the ingredients of which these are made up. The very small per-centage of these ingredients in any soil necessitates a minute analysis of every soil before it can be ascertained whether or not it contains any or what propor-

tion of these ingredients. But the reason for such minuteness in analysis becomes obvious when we consider the immense weights which have to be dealt with in practical agriculture; for example, every imperial acre of soil, considered as only 8 inches deep, will weigh 1884 tons, so that 0.002 per cent—that is, only a two-thousandth per cent, the amount of sulphuric acid in a barren soil—amounts to 80.64 lb. in the imperial acre!

"Potash and soda exist in variable quantities in many of the more abundant minerals, and hence it follows that their proportion in soil will vary according to the mineral which produced it. For the sake of reference, I have subjoined the following table, which shows the amount per cent of alkalis in some of these minerals, and likewise a rough calculation of the whole amount per imperial acre, on the supposition of a soil composed solely of these rocks, and of a depth of 10 inches, and the amount is abundant beyond conjecture.

Name of Mineral.	Amount per cent of Alkali.	Name of Alkali.	Amount per imperial acre in a soil 10 inches deep.									
			tons	cwt	qrs	lb	tons	cwt	qrs	lb		
Felspar, .	17.75	Potash,	422	18	2	8	—	—	—	—	—	—
Clinkstone, .	3.31 to 6.62	Potash and soda,	71	17	2	0	to	143	15	0	0	0
Clay slate, .	2.75 to 3.31	Potash,	35	18	3	0	to	71	17	2	0	0
Basalt, .	5.75 to 10.	Potash and soda,	17	0	0	0	to	25	7	3	7	7

"One unacquainted with chemistry will naturally ask the question—How is it that these alkalis have not been long ago washed away by the rain, since they are both so very soluble in water? The reason of their not being dissolved is the following, and it may in justice be taken as an example of those wise provisions of nature, whereby what is useful is never wasted, and yet is at all times ready to be abundantly supplied.

"These alkalis exist in combination with the various other ingredients of the rock in which they occur, and in this way have such a powerful attraction for those ingredients that they are capable of completely resisting the solvent action of water as long as the integrity of the mass is sustained. When, however, it is reduced to a perfectly impalpable powder, this attraction is diminished to a considerable extent, and then the alkali is much more easily dissolved. Now this is the case in soil, and consequently while the stony portions of the soil contain a vast supply of these valuable ingredients in a condition in which water can do them no injury, the impalpable powder is supplied with them in a soluble state, and hence in a condition available to the wants of vegetation.

"In the rocks which we have mentioned the alkalis are always associated with clay, and it is to this substance that they have the greatest attraction: it follows, therefore, that the more clay a soil contains, the more alkalis will it have; but at the same time it will yield them less easily to water, and through its medium to plants."

The following analysis of a soil, drawn up by Baumbauer of Utrecht, from a tract in North Holland gained by embankment from the

sea, without reference to its barrenness or fertility, is given by Mr Stephens, in order to show the great variety of substances contained in it, and also how important they are in the growth of plants:—

	Soil (surface).	Subsoil, 15 inches deep.	Subsoil, 30 inches deep.
Organic matter and water combined, . . . .	8.324	7.700	9.348
Humic acid, . . . .	2.798	3.911	3.428
Crenic acid, . . . .	0.771	0.731	0.037
Apocrenic acid, . . . .	0.107	0.160	0.152

"On comparing the constituents of such a soil as the above with the mineral ingredients obtained by incineration from the ashes of plants, it is found that plants withdraw from the soil chiefly its alkaline, mineral, acid, and earthy ingredients; and if all these were not essential to the very existence of the plants, they would

not of course be taken up by them; and as the plants constituting our cultivated crops withdraw those ingredients in a varied amount, it follows that unless the soils we cultivate contain them in ample amount and variety, it will be impossible for the plants placed above them to arrive at a perfect state of development of all their parts; for, chemically speaking, and rationally speaking too, soils cannot be expected to produce crops abundantly, unless they contain a sufficient supply of every ingredient which all the crops we wish to raise require from them.

“The practical purpose of all analyses of plants and soils should, therefore, be to make us acquainted with the constituents of every variety of cultivated crop at their different stages of growth, and to ascertain whether or not each soil in use contains a sufficient supply of such ingredients. The analysis of plants should have thus a twofold object—namely, to guide the cultivator in the treatment of the plants at the various stages of their growth, and to instruct him as to what quantity the ripe plant in its healthy state finally carries off of those ingredients from the soil.”

Professor Johnston, in “Lectures on Agricultural Chemistry and Geology,” observes, “The latter only of these two applications of such knowledge has hitherto been kept in view by chemists; and so little has been done in reference to it, that we scarcely know as yet what any one *entire* plant, when fully ripe, carries off from the soil. In reference to the former application, the few imperfect researches detailed in the preceding sections (of the second edition of his Lectures) contain all that we yet know. We may well say, therefore,” he concludes, “that our knowledge of the inorganic constituents of plants is yet in its infancy, and that our present opinions upon the subject ought, therefore, to be permitted to hang very loosely about us.”

The following table, showing the per-centage of mineral ingredients taken from the cultivated soil by some plants, is given by Mr Stephens:—

100 lb. of	ROOT OR TUBER.		LEAVES.	
	Undried.	Dried.	Undried.	Dried.
Potato, .	0.8 to 1.1	3.2 to 4.6	1.8 to 2.5	18 to 25
Turnip, .	0.6 to 0.8	6.0 to 8.0	1.5 to 2.9	14 to 20
Beet, .	—	6.3	—	—
Jerusalem artichoke, }	—	6.0	—	—
Carrot, .	0.7	5.1	—	16.42
Parsnip, .	0.8	4.3	—	15.76
Mangold- wurzeln, }	1.2	7.0	0.53	7.55
Cabbage, .	—	—	—	18.25

On the results given in the above table, together with three others of a similar nature by Mr Stephens, Professor Johnston makes the following observations: “The quantity of inorganic matter contained in the same weight of the different crops we raise, or of the different kinds of vegetable food we eat, or with which our cattle are fed, is very unlike; and the quan-

tity contained in different parts of the same plant is equally unlike. These results cannot be the effect of accident. They are constant on every soil, and in every climate; they must, therefore, have their origin in some natural law. Plants of different species must draw from the soil that proportion of inorganic matter which is adapted to the constitution, and is fitted to supply the wants of each; while of that which has been admitted by the roots into the general circulation of the plant, so much must proceed to and be appropriated by each part as is suited to the functions it is destined to discharge. And as from the same soil different plants select different quantities of saline and earthy matter, so from the same common sap do the bark, the leaf, the wood, and the seed select and retain that proportion which the healthy growth and development of each requires. It is with the inorganic as with the organic food of plants—some draw more from the soil, some less; and of that which circulates in the sap only a small portion is expended in the production of the flower, though much is employed in forming the stem and leaves.” Of the great utility of analysis Dr Ure observes, that “no system can be devised for the improvement of land independently of experiment; but there are few cases in which the labour of analytic trials will not be amply repaid by the certainty with which they denote the best methods of melioration, and this will particularly happen when the defects of composition are found in the proportions of the primitive earths. In supplying organic matter a temporary food only is provided for plants, which is in all cases exhausted by means of a certain number of crops; but when a soil is rendered of the best possible constitution and texture with regard to its earthy parts, its fertility may be considered as permanently established. It becomes capable of attracting a very large portion of vegetable nourishment from the atmosphere, and of producing its crops with comparatively little labour or expense.”

*Determining the quality of soils mechanically and empirically.*—The difficulties which present themselves to most cultivators in carrying out a scientific chemical analysis of soils have been noticed: we shall now briefly state more simple means by which the most important constituents of soils may be determined, so far, at least, as is applicable to cultivation.

The best practical directions on this head are those published in the “Encyclopedia of Gardening,” of which the following is an abbreviated extract:—

“The specific gravity of a soil may be ascertained, by introducing into a phial which will contain a known quantity of water equal volumes of water and of soil; and this may easily be done by pouring in water till it is half full, and then adding the soil till the fluid rise to the mouth. The difference between the weight of the soil and that of the water will give the result. Thus, if the bottle contains 400 grains of water, and gains 200 grains, when half filled with water and half with soil, the specific gravity will be 2—that is, it will be twice as heavy as water;

and if it gained 165 grains, its specific gravity would be 1825, water being 1000.

"The presence of clay and sand in any soil is known—the first by its tenacity, the other by its roughness to the touch, and by scratching glass when rubbed upon it.

"The presence of calcareous matter in soil may be ascertained by simply pouring any acid upon it, and observing if it effervesces freely. Muriatic acid is the best for this purpose. Calcareous soils, magnesian soils and clays, are, for the most part, softer to the touch than arenarous soils. To ascertain the quantity of calcareous earth present, dry soil thoroughly, and weigh 100 grains of it, which gradually add to 1 drachm of muriatic acid, diluted with 2 drachms of water, in a phial poised in a balance; the loss of weight will indicate the escape of carbonic acid, which will be 44 per cent of the quantity of calcareous earth in the soil.

"The presence of organised matter in any soil may be ascertained very satisfactorily by weighing it after it is thoroughly dried, then subjecting it to a red heat, and weighing it again—the weight so found will be the proportion of organic matter, and carbonic acid gas, if there should be any. The same object may also be attained by ascertaining the specific gravity of the soil, but with less accuracy.

"The presence of metallic oxides in a soil may generally be known by their colour. Ferruginous soils are red or yellow; cupreous soils interspersed with greenish streaks, &c. Cupreous impregnations of soils are rare, and the usual green matter in such soils as the *greensand* of English geologists appears to be coloured by iron, which is almost the only metallic impregnation in considerable quantity in any soil.

"The presence of salt, sulphur, coal, &c., may be known by the absence or peculiarity of vegetation, as well as by colour, and the appearance of the water of such soils. Saline soils may be distinguished by the taste; sulphureous soils by their smell when thrown on a hot iron; and the presence of coal by its fragments, which will be left after the soluble matters are removed by water and muriatic acid.

"The capacity of a soil for retaining water may be thus ascertained: an equal portion of two soils, perfectly dry, may be introduced into two tall cylindrical glass vessels, in the middle of each of which a glass tube has been previously placed. The soils should be put into each in the same manner, not compressed very hard, but so as to receive a solidity approaching to that which they possessed when first obtained for trial. If, after this preparation, a quantity of water be poured into the glass tubes, it will subside, and the capillary attraction of the soils will conduct it up the cylinders towards the top of the vessels. That which conducts it most rapidly, provided it does not rise from the weight of the incumbent column of water in the tube, may be pronounced to be the better soil."

"Soils, considered scientifically," says Dr Madden, "may be described to be essentially a mixture of an impalpable powder, with a greater or smaller quantity of visible particles, of all sizes and shapes. Careful examination will prove to

us that, although the visible particles have several *indirect* effects of so great importance that they are absolutely necessary to soil, still the impalpable powder is the only portion which *directly* exerts any influence upon vegetation. This impalpable powder consists of two distinct classes of substances; viz., *inorganic* or *mineral* matters, and *animal* and *vegetable* substances, in all the various stages of decomposition. A very simple method may be employed to separate these two classes of particles from each other; viz., the impalpable powder and the visible particles; and in so doing, we obtain a very useful index to the real value of the soil. Indeed, all soils, except stiff clays, can be discriminated in this manner. The greater the proportion of the impalpable matter, the greater, *ceteris paribus*, will be the fertility of the soil. To effect this separation, the following easy experiment may be performed: Take a glass tube, 2 feet long, closed at one end; fill it about half full of water, and shake into it a sufficient quantity of the soil to be examined to fill the tube about 2 inches from the bottom, then put in a cork, and, having shaken the tube well to mix the earth and water thoroughly, set the tube in an upright position for the soil to settle down. Now, as the largest particles are of course the heaviest, they fall first, and form the undermost layer of the deposit, and so on in regular gradation, the impalpable powder being the last to subside, and hence occupying the uppermost portion. Then, by examining the relative thickness of the various layers, and calculating their proportions, a very accurate mechanical analysis of the soil may be made."

*Colour of soils.*—Soils vary in colour from black to dirty white, the intermediate ones being red, blue, brown, light yellowish brown, &c. They derive these colours, for the most part, from the oxides of iron contained in them, and also from decomposing vegetable substances, which all surface-soils contain in a greater or less degree: some black soils may be totally devoid of iron altogether, but these are few. All very black soils, such as peat and deep deposits of vegetable mould, are inert; and hence so is old garden mould, long under cultivation and gorged with organic manure. The protoxide of iron is a powerful agent in communicating a black colour, sometimes, in stiff clays. White soils are chiefly over the chalk formation, and the sandy deposits found near the sea-shore are often of a yellowish white, both, however, darkened by the addition of organic manure.

Red soils, or rather dull brownish red, derive their colour from peroxide of iron.

Blue soils are found in the basins of stagnant water, and in deposits of great depth, such as the London basin of blue clay; they change colour to a darkish brown by exposure and cultivation.

Brown and light-yellowish brown-coloured soils are by far the most common as well as the most valuable; and although this colour is derived from oxide of iron, it does not often exist to a very injurious extent, excepting in gravelly soils of a binding nature. A greater variety of colour exists in subsoils; and the brighter these

are, the more injurious they are to the soil over them.

The effects of colour on soils are various, and have a considerable influence in regulating the quantities of heat absorbed from the sun's rays. The darker-coloured soils absorb most heat, while the lighter-coloured ones reflect most of that element. Much, however, of the absorbent property depends on the nature of the soil, whether it be free of superabundant water or the reverse; and hence a great difference exists in this respect between water-logged black peat and dry black soil containing abundance of organic matter, although the latter facilitates the preservation of temperature, in consequence of the vegetable and animal matter it contains, when heated to the same degree, cooling more slowly than a wet pale soil entirely composed of earthy matter; while stiff clay is with difficulty heated, and soon parts with the heat it acquires. Hence it may be considered the coldest of all soils. Chalks are heated with difficulty, but, being drier, when once heated they retain it longer, less being consumed in causing the evaporation of their moisture. Soils containing much carbonaceous or ferruginous matter acquire a much higher temperature from the sun than pale soils. From the experiments made by Schübler with the thermometer in the shade, sand of a natural colour indicated a temperature of  $112\frac{1}{2}^{\circ}$ , black sand,  $123\frac{1}{2}$ , and white sand,  $110^{\circ}$ , giving a difference of  $13^{\circ}$  in favour of a black colour.

Sir H. Davy ascertained that a black-coloured soil containing one-fourth of vegetable matter increased in temperature in one hour  $23^{\circ}$  by exposure to the sunshine; while a white chalk soil only gained  $4^{\circ}$  in the same time, and under the same circumstances. But the black soil, when removed into a shaded place, cooled  $15^{\circ}$  in half an hour; while the chalky soil only lost  $4^{\circ}$  in the same time, and under the same circumstances.

Most physiologists agree that the pure soil, without organised matter and water, is of no other use to plants than merely affording them a fixed abode, and a medium by which they may fix themselves to the globe. Soil is also necessary to plants by enabling them to obey those laws of nature by which their roots are kept below the surface, and their leaves exposed to the free atmosphere.

"It is commonly supposed that plants derive the whole of their food from the soil, but this is a great error. It is a fact well ascertained by chemical experiments, that plants derive the greater part of their nourishment from the air, although the soil is equally essential to their growth."—SOLLY in *Rural Chemistry*.

In general, much more depends on the texture of a soil, and its capacity for retaining or parting with water and heat, than on its chemical composition.

*Subsoils* are of vast importance, because on them depends, in a great measure, the capacity of the surface-soil for retaining or parting with water and heat. Of these, the worst is clay, kept wet with subterranean water, and the best are those of clay resting on gravel or porous rock. The latter of these is the best of all

for a garden, because, while the water finds a ready means of escape through the fissures in the rock, the roots of the trees are at the same time prevented from extending too deep, and made to take a horizontal direction nearer the surface, and also prevented from extending into a cold and uncongenial soil, causing late excitement of the sap in spring, immature ripening of the wood and buds in autumn, and consequent paucity of fruit and premature decay in the trees. The soil, for reasons already stated, is, under such circumstances, much increased in temperature, producing earlier crops of culinary vegetables, and those of much better quality, on account of the greater rapidity of their growth. Gravelly subsoils are not always to be depended upon, for these are sometimes placed over basins of impervious clay, from which water cannot escape until it rises as high as the margin of the basin itself, leaving the gravel thus saturated with water. Again, gravel abounding in oxide of iron is a bad subsoil, and often occurs. Next, therefore, to a rocky bottom, that of clean alluvial gravel is to be preferred; and in such all the productions of a garden will prosper, and that often when the climate is indifferent. Notwithstanding these advantages, how seldom, in practice, is this attended to. Much labour and expense are gone into the improvement of the upper soil, while the lower and more important is left in its natural state. Artificial subsoils are seldom thought of, although of their advantages no one can doubt; and as nature has pointed out to us that an open porous one is the best, our first attempt at garden-making should be to imitate her in this respect. We have shown in vol. i., p. 29, 31, how an artificial subsoil can be formed for fruit-tree borders; and as experience has proved the great utility of these, the enlightened horticulturist will at once see the feasibility of extending the same process under the whole of his garden. We may here only state, that where sufficient drainage material may be difficult to procure, recourse may be had to concreting, taking care that a sufficient number of drain-tiles be laid underneath for the free escape of the water, which should find its way into them through apertures left in the concrete floor. It must, however, be admitted that such excessive drainage is not applicable to all situations alike, so far as the removal of water alone is concerned; but so far as keeping the roots near the surface, and preventing their extending into a bad subsoil, the rule is absolute. Along the eastern coast of Britain, where the annual fall of rain is less than half of what it is on the western, this excessive drainage is of much less importance, unless in low situations where subterranean water abounds, and where it cannot be conveniently drained off.

*Mineralogical quality of soil.*—The temperature and proper amount of moisture in a soil is of far greater importance to the successful culture of plants than its mineralogical structure, and this has reference to hardy as well as to tender plants. "I entertain little doubt," Dr Lindley observes (in "Theory of Horticulture"), "that the time is at hand when it will be considered

quite as necessary to furnish heat for the soil as for the air; not, however, heat without moisture, for that would evidently produce much greater evils than it was intended to cure, as has indeed been found by inconsiderate experimenters. I quite agree," continues the doctor, "with Mr Writgen in believing that it is the temperature and moisture of a soil, much more than its mineralogical quality, that determine its influence upon vegetation."

*Moisture in the soil.*—"Water," continues the same authority, "is one of the most important elements in the food of plants, partly from their having the power of decomposing it, and partly because it is the vehicle through which the soluble matters found in the earth are conveyed into the general system of vegetation. Its importance depends, however, essentially upon its quantity. We know, on the one hand, that plants will not live in soil which, without being chemically dry, contains so little moisture as to appear dry; and, on the other hand, an excessive quantity of moisture is, in many cases, equally prejudicial. The great point to determine is, the amount which is most congenial to the constitution of the plant. The effect of continuing to make plants grow in a soil more wet than suits them, is well known to be not only a production of leaves and ill-formed shoots, instead of flowers and fruit, but, if the water is in great excess, of a general yellowness of appearance, owing, as some chemists think, to the destruction by the water of a blue matter, which, by its mixture with yellow, forms the verdure of vegetation. If this condition is prolonged, the vegetable tissue enters into a state of decomposition, and death ensues. In some cases the joints of the stem separate, in others the plant rots off at the ground; and all such results are increased in proportion to the weakness of light and the lowness of temperature. Decandolle considers that the collection of stagnant water about the neck of plants prevents the free access of the oxygen of the air to the roots; but it seems to me," says Dr Lindley, "that much more mischief is produced by the coldness of the soil in which water is allowed to accumulate. It seems also probable that the extrication of carburetted hydrogen gas is one cause of the injury sustained by plants whose roots are surrounded by stagnant water; but upon this point we want much more satisfactory evidence than we yet possess."

*Stones are valuable in all soils*, as they, in general, are composed of the same material as the soil itself, and, indeed, may be considered as the soil in a previous state. By their gradually crumbling down by the action of air, frost, and moisture, they are continually adding new impalpable matter to the soil. As a considerable portion of this impalpable matter is annually consumed by plants, were it not for the presence of stones the soil would ultimately become sterility itself. The practice, therefore, of raking off stones is just removing so much of the soil itself; and the ill effects of this have been long ago observed by cultivators, while they were ignorant of the cause—so much so, it has been

stated that some farmers, finding their land so much deteriorated after the removal of the stones, returned them again, after which the soil regained its former fertility.

*Impalpable matter in the soil*—that is, matter not to be perceived by touch—is of vast importance to vegetation, and is a product of both organic and inorganic matters. Its functions are exceedingly complicated, and are thus spoken of by Dr Madden: "In this portion of the soil, the mineral and organic matter are so completely united, that it is quite impossible to separate them from each other; indeed, there are weighty reasons for believing that they are chemically combined. It is from this portion of the soil that plants obtain all their mineral ingredients, and likewise all their organic portions, in so far as these are obtained by the roots; in fact, plants receive nothing from the soil except water, which has been associated with that portion which is at present engaging our attention.

The particles forming the impalpable matter are in such close apposition that the whole acts in the same way as a sponge, and is hence capable of absorbing liquids and retaining them. It is in this way that soil remains moist so near the surface, even after a long-continued drought; and I need not say how valuable this property must be to the plants, since by this means they are supplied with moisture from below, brought up by the capillary action of the soil during the heat of summer, when otherwise, unless artificially watered, they would very soon perish.

Another most useful function of this impalpable matter, is its power of separating organic matter from water in which it has been dissolved. Thus for example, if the dark-brown liquid which flows from a dunghill is taken and poured on the surface of some earth in a flower-pot, and a sufficient quantity added to soak the whole earth, so that a portion flows out at the bottom of the pot, this latter liquid will be found much lighter in colour than before it was poured upon the earth; and this effect will be increased, the nearer the soil approaches in its nature to the subsoil. Now, as the colour was entirely owing to the organic matter dissolved in it, it follows that the loss of colour is dependent upon an equivalent loss of organic matter; or, in other words, a portion of the organic matter has entered into *chemical combination* with the impalpable mineral matter, and has thus become soluble in water. The advantage of this is, that when soluble organic matter is applied to soil, it does not all soak through with the water, and escape beyond the reach of the roots of the plants, but is retained by the impalpable portions in a condition not liable to injury from rain, but still capable of becoming food for plants when it is required." Hence liquid manure may be applied to the soil at any period of the year—an opinion that has been disputed by those who have not fully considered the matter.

*The surface of soils* is of vast importance, because on its inclination greatly depends the proper amount of moisture retained by the soil for the growth of plants. If too steep, it throws off the rain too rapidly; and if too flat, it often retains

too much moisture, and occasions a loss of heat by evaporation. But, on the other hand, surfaces with a considerable inclination towards the south are much more highly heated by the sun's rays than those that are flat, because they are placed at a better angle of elevation for action of the sun's rays upon them. "If the actual increase of temperature produced by the perpendicular rays of the sun beyond the temperature in the shade be between 45° and 65°," as has been computed by Schübler to be often the case in clear summer days, this increase would be only half as great if the same light spread itself in a more slanting direction over a surface twice as large. Hence it is sufficiently explained why, even in our own climate, the heat so frequently increases on the slopes of mountains and rocks which have an inclination towards the south.

### § 3.—THEIR IMPROVEMENT.

All soils are capable of improvement, so as to render them more fit for the purposes of remunerative cultivation. The principal operations in connection with this are draining, pulverisation, consolidation, alteration of their constituent parts, exposure to atmospheric influence, &c.

*Draining* is the first and principal means of improving a soil, and without it all other attempts will prove of no avail. The number and form of drains will depend on local circumstances, of which the texture of the soil is by no means the least worthy of careful study. The leading or main drains in gardens should invariably be placed under the walks, and the overflow drain carried beyond the enclosed boundary. With this drain all the others should communicate. The depth of drains will depend on local circumstances, but it is better that they be deep than otherwise, so that they may not be disturbed by trenching or other excavations. Those in connection with the cellars, stoke-holes, &c., should be sufficiently deep to thoroughly clear them of water; and in their first formation they should be laid even to a greater depth, to provide against the chance of sinking either the one or the other at a future time.

The principal drains in a garden, as well as in all dressed grounds, should be laid down in the most substantial manner possible, in the first instance, and their lines correctly marked on a plan upon a large scale, that they may be easily got at in case of accident, and their direction should be such as to come under permanent buildings, &c. as seldom as possible. Without due attention to these points, much trouble and expense may be incurred, besides the derangement attendant on breaking up the ground afterwards. Main drains often offer a convenient entrance for rats and other vermin; their mouths should be guarded with efficient iron gratings; and as a farther precaution, drain-traps should be placed in them at convenient distances.—(Vide vol. i., Sect. TANKS.)

There is no operation in the whole catalogue of improvements in which so much gross igno-

rance has been displayed as in that of draining; and, in many cases, strict adherence to the dicta laid down by professed drain-doctors has amounted to time and capital thrown away. A universal system of draining in all soils, and under all circumstances, is about as unreasonable as a universal medicine to be administered for all diseases, and to all ages, sexes, and constitutions.

The advantage of draining is twofold: the first is the elevating the temperature of the soil by the abstraction of superfluous moisture, and hence admitting the rays of heat to occupy those spaces formerly charged with water;—the soil thus becomes warmed by conduction; and the atmosphere above, by a diminution of evaporation. Air, from which the roots of plants derive so much advantage, is admitted to them, the soil and atmosphere above it becoming materially changed for the better. So important a matter is this, in relation to horticulture, that many now form their borders for their finest fruit-trees upon the top of vaults kept constantly filled with air; and few exotic fruit-houses are now built without abundance of subterranean ventilation being provided. In wet districts, and where the subsoil is a close tenacious clay, the process of vaulting might be carried over the surface of a large garden, and with the most beneficial effects. Next to that would be the formation of a bed of loose stones, scorie, or other similar material, between the soil and subsoil, not only to act as a general drainage, but also as a means of admitting air to the roots of plants. In such a stratum drain-tiles should be laid in lines 6 or 8 feet asunder, and made to communicate with cross ones, which latter should have a free communication with the external air. On wet clayey retentive subsoils, this would, next to vaulting over the whole area, be the most effectual means of thoroughly improving the soil, so far as the admission of air and the abstraction of water are concerned. The temperature of a heavy soil in a garden in Hampshire has been raised 15° by drains 4½ feet deep. Drainage not only permits the heat to penetrate deeper into the soil, but it also enables it to retain it a longer time. Mr Shearer has clearly shown the effect of vaulting, which is drainage carried to its fullest extent, in the case of the fruit-tree borders in the gardens at Yester—a cold locality, at the base of the Lammerruir range—to be equal to 9° of increased temperature—(Vide vol. i. p. 31.)

Now, in all naturally cold countries, whatever tends to increase the temperature of the air or of the soil must be regarded as being of the utmost importance to vegetation; and as draining produces this effect, its importance must be of the greatest consequence to man, and that importance increases as we recede from the equator. For, although exactly the same depth of rain should fall annually in lat. 1° south that falls in lat. 50° north, the soil in the latter will be many times wetter than in the former, on account of a greatly diminished amount of evaporation, in consequence of our greater distance from the sun. The importance of draining has of late years been fully acknowledged; and

although the *modus operandi* has been treated by some as a science, still by far the greater number of operators have acted upon the most incorrect principles.

Few superficial observers are perhaps aware of the great difference in temperature between thoroughly-drained soil and that in which superfluous water is allowed to lodge. Dr Lindley asserts—and, we believe, from very accurately made experiments—that the difference in summer is from 10° to 20°. The reason for this is, that heat cannot be transmitted downwards through water. “Thus neither the heat of the sun nor the warm rain can penetrate to the roots of plants in ill-drained land; even boiling water poured on the surface would have no effect in warming soil on which cold stagnant water naturally stands. Air also cannot reach the roots of plants grown in soil of this nature. It is as important to admit air to the roots of plants as to their leaves—both extremities of plants feed on air, *the roots more than the leaves.*”

—*Lindley.* Place a plant in a situation where air can get no access to its leaves, and they fall off, to be followed by the decay of the stem: roots, under the same circumstances, will gradually shrink and die. The same high authority elsewhere observes, that “many believe that the whole advantage (of draining) consists in removing water; but water is not in itself an evil—on the contrary, it is the food of plants, and its absence is attended with fatal results. It is the excess of water which injures plants, just as an excess of food injures animals—with this difference, that animals can refuse what is hurtful to them, while plants have no choice, but must take into their systems whatever is in contact with the spongioses of their roots. The latter are, therefore, more readily gorged than the former. But undrained land is not merely wet; it is water-logged. All the interstices between the particles of earth being filled with water, air is necessarily absent, except that small quantity which is dissolved in the water. In this way plants are deprived of the most essential part of their food; but when the water is removed, the air takes its place, and holds in suspension as much water as the roots can thrive upon; for it is not water in a fluid state that plants prefer: it is when it has assumed a state of vapour that they feed upon it best; so that the removal of water permits air, and air-borne vapour, the best of all food for roots, to take place.”

As to the depth and the distance between the drains, opinions are still, and, we believe, ever will be, at variance; the case must therefore be as it has been—left greatly to the judgment of the operator. The following very sensible remark has been made by Mr Stephens, in “The Book of the Farm,” vol. ii. p. 617, on this subject: “With our present experience, however, I do not see the utility of cutting drains as deep as 6 or 8 feet, merely to extend the space between them, when perhaps the same effect might be obtained by 3 or even 4 feet drains at narrower intervals, unless very deep drains at very wide intervals can be executed with more economy. Experience has yet much to elicit in regard to the distance that should be between

sub-drains of different depths in different soils, to effect the best results.”

*Pulverisation.*—Next in importance to rendering the soil dry by draining, is the process of pulverising, which is effected by trenching, digging, grubbing, stirring, &c. The depth to which this operation should be carried, must of necessity depend on the soil and subsoil. Sir H. Davy observes, “In rich clayey soils it can scarcely be too deep; and even in sands, unless the subsoil contains some principles noxious to vegetation, deep comminution should be practised. When the roots are deep, they are less liable to be injured, either by excess of rain or drought.” Trenching has a most beneficial effect on all soils of a depth consistent with the best principles of horticultural culture, by reversing the surface, and mixing and transposing the whole mass operated on. It improves the temperature of the soil, renders it capable of allowing the rain-water to filter through it, and enables the roots of plants to travel freely in search of food. “By changing the surface, fresh soil is exposed to the action of the weather; by changing the position of all the parts, new facilities for chemical changes are produced; and by loosening the whole mass of the soil, air and rain are more readily admitted. By loosening soil, the air is admitted among its particles, and confined there; and hence it becomes a non-conductor of heat, and is consequently warmer in winter, and cooler in summer, than if it were in one firm mass. By the confinement of air in the soil, the heat imparted to it by the sun during the day is retained, and accumulates in all free open soils to such a degree as to raise their temperature over that of the air, especially during night. From thermometrical observations made at different places, it appears that the mean temperature of the soil, at about one foot below the surface, is somewhat higher naturally than the mean temperature of the atmosphere on the same spot; and hence we may reasonably suppose that, by draining and pulverisation, the temperature of the soil may be permanently increased, as well as that of the atmosphere.”—*Sub. Hort.*, p. 55. The atmospheric air which becomes buried in the soil during the process of trenching and deep-digging—in the latter case in a less degree—becomes decomposed by the moisture in the soil, and the following chemical changes take place: “Ammonia is formed by the union of the hydrogen of the water with the nitrogen of the atmosphere, and nitre by the union of the oxygen and nitrogen. The oxygen may also unite with the carbon contained in the soil, and form carbonic acid gas and carburetted hydrogen.” Heat is given out during these processes; “and hence,” as Dr Darwin, in “*Phytologia*,” sect. 2, remarks, “the great propriety of cropping lands immediately after they have been comminuted and turned over; and this the more especially if manure has been added at the same time, as the process of fermentation will go on faster when the soil is loose and the interstices filled with air than afterwards, when it becomes compressed by its own gravity, the relaxing influence of rains, and the repletion of the partial vacuums

formed by the decomposition of the enclosed air. The advantages of the heat thus obtained in exciting vegetation, whether in a seed or root, especially in spring, when the soil is cold, must be very considerable." By a judicious system of trenching, fresh soil will be brought into immediate contact with the roots of plants—a circumstance of so much importance in culture, and so well known, as to require no further comment. "The free admission of atmospheric air to soil is also necessary for the decomposition of humus, or organic matter, by which carbonic acid is formed. The atmospheric air is also a great source of nitrogen, which has been lately found in all plants, and more especially in the spongioles of the roots. The soil also, when loosened, becomes a rapid conductor of water; and supposing the texture of the soil to be suitable for culture, it will retain a sufficient quantity of moisture for the purpose of vegetation, and allow the escape of what is superfluous by filtration into the subsoil, or into the underground drains which have been formed as a substitute for a porous substratum. The mere act of pulverising any soil has a tendency to improve its texture, more especially if the operation be frequently repeated. In summer, by exposure of a soil to the air, the particles are separated by the evaporation of the water in their interstices by heat; and by exposing a soil to the frosts of winter, the particles are separated by the expansion of the water in the act of freezing. Clayey soils containing iron are in an especial manner improved by exposure to the atmosphere, the iron being still further oxidised, and thus acting like sand in separating the particles, as well as being less likely to be rendered soluble by the addition of saline matters."—*Sub. Hort.*, p. 55.

Jethro Tull, one of our earliest writers on improved husbandry, estimated the process of pulverisation so highly, that he fancied no other assistance was required in the preparation of the soil for crops; in this, however, he overrated this important operation. Du Hamel, entertaining somewhat similar views with Tull, decidedly proved that the multiplication of the fibres of plants is as the inter-pulverisation of the soil; but the advantages thus gained by vegetables, by the increased number of their fibres, must depeud a good deal on the quantity of food within their reach. However much the two authorities last quoted may have overrated pulverisation, one thing is certain, that where it is carried out to its fullest extent, the quantity of manure required is very materially lessened. Nevertheless, as garden soils require to be loosened to a considerable depth, to allow the roots of many plants to descend, it also follows that enrichment should be carried to the same extent, and the more so when we consider that the roots of all plants collect their nourishment from their extreme points, and that many of them, such as beet, parsnip, &c., derive their food at a depth of 2 or 3 feet below the surface.

*Digging, ridging, and trenching.*—These are important operations, performed, in general, only by commercial growers, who have to make the most of their ground; and as they carry out these to a great extent, it is quite evident that

they see the propriety of so doing. In private gardens they are much neglected; and hence one of the causes why the productions in them are so inferior to the others. In ordinary digging, the spades used in the market-gardens around London are 13½ inches long and 10 inches broad, while those used in private gardens are seldom more than 10 inches by 7½ inches, the former loosening the ground to a greater depth. Nor is even this deemed sufficient; almost every portion of ground is single or double trenched annually.

*Garden spades* are of various forms, and adapted to various purposes; but, until of late years, little improvement has been made in them. For all purposes of lifting the soil, or digging pits, they are better than forks; but for the mere purpose of pulverising by loosening, and for digging up roots, and digging amongst plants and trees, broad-pronged forks are preferable.

*Lindon's cast-steel spade* is the best: the blade is thinner, yet stronger, than the garden spade in ordinary use, thus constituting an important point in its favour, because one-third less power is required to force this thin-bladed tool into the ground than the thick and clumsy spade hitherto used. The handle, also, in Lindon's spade is improved by being curved a little forward, giving it a better leverage than if it were straight, and rendering less stooping necessary in using it. The blade is highly tempered, which renders it an excellent cutter of roots, working clean, and wearing well. It is known also as the Birmingham spade.

*Black's spade* is in much repute in Scotland, as being of excellent material. It is very similar to Lindon's in form—scarcely, however, so light, and probably less highly tempered. They are manufactured at Ford Forge, Ford, Northumberland.

The sizes of the above spades are,

No. 2.—7½ in. bd. at bottom, 7½ in. at top, and 12 in. deep.	8	12½
No. 3.—7½ . . . . .	8	12½

No. 5.—8½ . . . . .	9	13½
No. 6.—8½ . . . . .	9½	14

*The prong spade.*—This implement is much used in some parts of Kent, and also in Cheshire, where it is called a "mule," from the circumstance of its combining, as it were, the common three-pronged fork and the common spade. In form it is a three-pronged fork with a spade handle, the points of the prongs being united together by a slip or strap, about 1½ inches wide, of steel welded to them, which forms the face or cutting part. It is lighter than the common spade, and well adapted for digging purposes.

It has been remarked, as one advantage arising from this deep-digging and trenching, that slugs and other insects are comparatively of rare occurrence in such grounds, possibly from their eggs and larvæ being buried too deep to become hatched by the solar heat near the surface. There can be no doubt, the deeper the soil is dug, the more fitted it is for productive crops; evaporation is promoted, a free and more extended sphere is offered to the roots, which enables them to range farther in search of food, and the soil becomes much less exhausted by

even succeeding crops of the same kind being grown upon it, an effect which must ensue when the depth is limited to 9 or 10 inches. Rotation of crops, so much insisted on by most cultivators, is, under this deep-trenching system, a matter of very unimportant consideration. No doubt, when the soil is naturally thin, and rests on a bad subsoil, it would be injudicious to trench so deep, at least at the commencement of its cultivation; because that portion which is really sufficiently fertile to produce moderate crops would be entirely buried, and a soil totally unfit for most plants would be brought to the surface. The improvement of such a subsoil, if sufficiently dry, can, however, be progressively accomplished by bringing up a portion of it at each digging, and incorporating it with that already formed, so that, in course of time, most soils may be rendered deep and fertile to any reasonable extent. Thin or shallow soils are greatly improved by a system of trenching much used by us, which, without bringing the bad subsoil up, yet loosens it to a considerable depth, and that without the expenditure of much manual labour. The process is as follows: At one end of the piece, open a trench not less than 3 feet in width, and as deep as the soil is already made, removing the earth taken out to the opposite side, for filling up the last trench. When the first trench is opened—say to the depth of a foot or more, according to circumstances—commence picking up the bottom, allowing it, however, to remain where it is. For this purpose we use picks made on purpose, the prongs of which are 20 inches in length; with these the subsoil is torn up and loosened to the depth of 18 inches, if the operation is not interrupted by rock. This, with the 12 inches of surface-soil already removed, gives us a depth of 2½ feet at the expense of actually removing 1 foot. It is a good plan to lay over the subsoil thus broken up a good coating of undecayed dung, which, in itself, improves the soil beneath, and affords nourishment to the roots of the crops when they descend to that depth. One of the great evils arising from a rich surface and an impoverished subsoil is, that the roots are pampered, and probably, in some cases over-fed, in their earliest stage of growth, and while the plants are small and require less nourishment: when they have attained, say half their size, and consequently stand in need of a proportionate amount of food, their roots, having passed through the rich soil, enter into that in which little or no nourishment for them is to be found. The consequence is, the plants sustain a sudden check, from which they never afterwards recover, but begin to assume a sickly worn-out appearance, run up to seed, or cease to increase in size, and ultimately die of sheer starvation.

During winter, when the ground is unfrozen, and when neither too wet or covered with snow, digging, ridging, and trenching should be proceeded with; it is the most profitable employment men can be engaged in. Every piece of ground, as soon as it is cleared of its crop, should be operated upon in one or other of these ways; and whichever be adopted, the

rougher the surface can be thrown up, the better, so as to expose the largest possible extent to the action of the weather. All manurings, without such operations as these, are of little avail; and these, even with a very limited supply of manure, will secure excellent crops. Ridging is a species of deep-digging or trenching, where the soil is thrown up in parallel ridges; it is found valuable in strong tenacious soils, as it presents the ground so ridged up to the action of frost better than when the surface is left more level.

The purpose of trenching is to deepen the soil by breaking into the subsoil, and improving that, as well as bringing part of it at each operation near to the surface, and amalgamating it with the soil, which has already been probably over-cropped. It promotes filtration and the descent of solar heat; it gives scope to the roots, and affords them a broader pasturage; it supplies rest to an already over-wrought soil, and brings into action one that has not probably as yet contributed the least share towards the sustenance of plants. In fact, it is cultivation upon a grand and high-culture principle. The more a soil is disturbed, and the deeper that disturbance is carried, the better, and the more manifest will its improved state be, even in the general acceptance of soil management. A very sensible practical writer, J. B., in the "Cottage Gardener," vol. i. p. 6, observes, "A soil would never get exhausted, if managed with skill, but would continue to improve in depth and fertility in proportion to the industry bestowed upon it. The food of plants, it is true, may be exhausted from the soil by a repetition of cropping with any one family of plants, if we neglect the application of such fertilisers as may have been taken from the soil by that family; but no part of the growing season is required for the soil to rest, or lie fallow, if judiciously managed by a successional varying of the crops, or supplying to them such food as may be a compensation for what has been taken off by the previous crops. The first object to be attained for securing a certain and profitable return of produce from the soil must be thorough drainage; the next object is *breaking into the subsoil* to the desired depth—not without first considering whether it is proper and profitable to shift and turn up the subsoil at once to the influence of the atmosphere, or whether it is best to break into it well first, by shifting the surface-soil, and allowing the subsoil to remain, to receive, first, the beneficial influence of the atmosphere; and then, at the next trenching, a portion of the subsoil may be safely stirred up and mixed with the surface-soil: this practice, continued for every succeeding crop, will establish a healthy fertilising surface-soil to any desired depth."

*Bastard trenching* is an excellent plan where the soil is too thin to admit of thorough trenching. In performing the operation, a trench is dug about a yard in breadth; indeed, no trenching should be of a smaller breadth, as, the wider the trenches are, the less chance is left to careless operatives of leaving dykes, or undisturbed portions of soil, between each trench. One full spit and a shovelling is then taken out, and car-

ried to the end where the operation is to finish. Lay a good dressing of dung on the bottom of the opened trench and dig it deeply in, then fill in with the top spit and shovelling of the next trench, which serve in the same manner, and so on till the whole is finished. By this mode the good soil is kept still on the top, and the subsoil is enriched and loosened at the same time, providing nourishment to the roots, and inducing them to descend in search of it. In time, this improves the soil to a sufficient depth for ordinary purposes, allows the rain to penetrate downward, and prevents the crops from suffering from drought. The only objection to it is that little change takes place in the soil, the top remaining at the top, and bottom at the bottom. Strong soils are rendered more open by it, the capacity of absorbing moisture is increased, and the surface is rendered drier.

In trenching, besides the amelioration of the soil by the mechanical operation of loosening, mixing, and turning over, other advantages should be aimed at; as, for instance, where it is of a strong retentive description, river or any sharp sand, lime-rubbish, the refuse chippings of soft sandstone incorporated with it, will be found of vast importance. In soils of an opposite character, or such as are denominated light, hot, dry, and hungry, abounding to an extreme in sand, and deficient in vegetable matter, clay, turfy peat, vegetable mould, marl loam, &c., should be added. Indeed, anything that can be procured of a diametrically opposite character to either of these soils, if added, will improve them. Clay, if very strong, may be advantageously laid on the surface in autumn, and when broken down by the winter frosts, will be in excellent condition to incorporate with the soil. Changes thus effected will be far more lasting and beneficial in their effects than all the manure that can be applied without them.

*Consolidation* is a species of soil-improvement the very opposite to pulverisation. It nevertheless sometimes becomes necessary, as in the case of light spongy peat-soil and very light sand. Neither of these, however, are often met with in garden culture. Compression is employed when seed is sown in dry weather upon light soils, and is effected by treading or rolling. Deep-digging and trenching, where the soil admits of it, should not, however, be disregarded, the operation of compression being confined to the surface only.

*Alteration of the constituent parts of soils.*—This is a species of improvement of vast importance, and consists in adding or subtracting those ingredients in which they are deficient or possess in superabundance. This species of improvement, in the present case, we will consider with reference only to an alteration of its texture, and observe that sandy soils will best be improved by the addition of alumina or clay, and strong clayey soils by an admixture of sand; and in both cases lime should be added, as no soil can be permanently fertile without alkaline matter. A much smaller quantity of clay applied to even a drifting sand will consolidate it,

and convert it into a good working loamy soil, than of sand to produce a like effect upon strong clay. Peat or other vegetable matter added to sand will enrich it, by supplying organic or vegetable matter in which the sand is deficient: but although this increases its fertility, it adds little to its texture; it may, therefore, be added as a compound mixed with clay and lime. Light sand, on a subsoil of loam or clay, will be improved by trenching so deep as to bring up a sufficient proportion of the clay to the surface; and peaty soils will be improved by the addition of sand, as well as of clay and loam. The quantity of one soil to be added to another, so as to render its texture perfect, can only be determined by experiment. The following is given as a practical example: "If we take an extreme case, and suppose that any given soil is so sandy as to require the addition of one-sixth its bulk of clay, or so clayed as to require one-sixth of its bulk of sand, then, in the case of a kitchen-garden, when the soil is 3 feet deep, every square foot of the clayey surface will require the addition of half a cubic foot of sand; and, in the case of a lawn, where the soil is 1 foot in depth, every square foot of sand will require the sixth of a cubic foot of clay. To cover a statute acre with soil to the depth of 1 inch, will require 121 cubic yards. Hence, to add 2 inches to the soil of a garden of 1 acre, exclusive of the space occupied by the walks, would require 242 cubic yards or cartloads. It frequently happens that a sandy or gravelly soil is incumbent on a bed of clay, and the contrary. In either of these cases, the supply of the required soil may be obtained by digging pits, or sometimes even by deep-trenching. The earth thus obtained will generally be without organic matter, but that can be supplied afterwards by manuring. Where the soil required for the improvement of another soil can be obtained in the state of surface-soil, the effects produced will be the more immediate for the organic matter that such soil contains; but even when it is obtained from the subsoil, the change in the condition of the soil to which the new soil is applied will soon be rendered obvious, though not so much the first year as it will be in two or three years afterwards, when the amalgamation of the two soils is more complete. Much of the effect of adding one soil to another will depend on their intimate mixture, and this can be best effected by repeated trenchings or diggings in dry weather, and when both soils are as nearly as possible in a state of dry powder. This point is of great importance, particularly when the soils mixed together contain a good deal of organic matter, because, if a very intimate mixture of both soils is not effected, they will, from the difference of their specific gravities, in a few years separate into two different strata. There is, indeed, a constant tendency to do this in all soils under culture, and more especially in all such as have been improved by admixture. This takes place in consequence of the softening of the soil by rains, by which the particles are, in a manner, held for a time in suspension, and the heaviest gradually take a lower place than these which are lighter. Hence the necessity of digging or trenching such soils

occasionally to the depth to which they have originally been improved."—*Sub. Hort.*, p. 52.

*Exposure to atmospheric influence.*—The action of the atmosphere effects important changes on soils. Indeed, as has been already stated, some trace the very origin of soils to atmospheric causes. Some of the advantages soils attain from exposure to the atmosphere have been noticed under the head *Pulverisation*. The others are effected by altering the position of their surface, by throwing it up into narrow ridges, deep-digging, and leaving the surface as rough as possible, frequently stirring it with the hoe, and tearing it up, where the soil is hard or tenacious, with the pick, or, still better, with Glendinning's pick-fork, *vide* fig. 85. The effects of all these are to render the surface open and pervious to solar heat, frost, and rain, which, acting by expansion, contraction, &c. of its parts, break it down, and render it more fitting for the growth of plants. "The influence of the sun's rays upon any plane are demonstrated to be as their number and perpendicularity to that plane, the effects of the atmosphere being excepted. Hence one advantage of ridging land, providing the ridges run from north to south; for, on such surfaces the rays of the morning sun will take effect sooner on the east side, and those of the afternoon will remain longer in operation on the west side; whilst at mid-day his elevation will compensate, in some degree, for the obliquity of his rays on both sides of the ridge."—*Encyc. of Gard.*, p. 477. Another advantage such an operation on surfaces has is, that the soil will dry sooner than if left undisturbed, on account of a freer evaporation going on. The air, upon which so much of the success of cultivation depends, will be admitted more readily to the roots of plants; and when we consider that they derive so much of their support from that element, the necessity of admitting it into the ground largely will be the more apparent.

*Burning soils*, with a view to their improvement, is an important matter in preparing land for planting, laying down as lawns, &c., and has of late been strongly recommended for almost all garden purposes.

The theory of burning soils rests entirely on chemical doctrines, of which Sir H. Davy and others have given clear elucidations. The advantages of burning "are, that it renders the soil less compact, less tenacious, and less retentive of moisture; and when properly applied, may convert a matter which was stiff, damp, and in consequence cold, into one powdery, dry, and warm, and much more proper for a bed for vegetable life."—*Encyclopedia of Gardening*, p. 477. The chemical change which takes place in soils subjected to the process of torrefaction, is stated by Sir H. Davy to be as follows: "The bases of all common soils are mixtures of the primitive earths and oxide of iron; and these earths have a certain degree of attraction for each other. To regard this attraction in its proper point of view, it is only necessary to consider the composition of any common silicious stone. Felspar, for instance, contains silicious, aluminous, and calcareous earths, fixed alkali and oxide of iron, which exist in one com-

pound, in consequence of their chemical attraction for each other. Let this stone be ground into impalpable powder, it then becomes a substance like clay; if the powder is heated very strongly, it fuses, and in cooling forms a coherent mass similar to the original stone; the parts separated by mechanical division adhere again in consequence of chemical attraction. If the powder be heated less strongly, the particles only superficially combine with each other and form a gritty mass, which, when broken into pieces, has the character of sand. If the power of the powdered felspar to absorb water from the atmosphere before and after the application of the heat is estimated, it is found much less in the latter case. The same effect takes place when the powder of other silicious and aluminous stones is made the subject of experiment; and two equal portions of basalt ground into impalpable powder, of which one-half had been strongly ignited, and the other only exposed to a temperature equal to that of boiling water, gained very different weights in the same time when exposed to air. In four hours the one had gained only two grains, while the other had gained seven grains. When clay or tenacious soils are burnt, the effect is of the same kind; they are brought nearer to a state analogous to that of sand."

There is no doubt something startling to the mind of the practical cultivator in the idea of burning soil, not taking, at the same time, into consideration that the process is not recommended as applicable to all soils, but only to some; and these are such as contain a superabundance of vegetable matter in a dead inert state like most peat soils, and those requiring more powerful agencies than that of mere working with the spade to bring them to a state more useful to plants, such as strong clays and tilly soils. Upon both of these the operation of burning has been attended with marked advantage. In connection with horticulture, there is another class of soils that are benefited by such an operation: these are old garden soils, glutted with organic matter by the yearly application of manure-dung, the lapse of ages, and at the same time replete with destructive insects, in all their various states of transformation from the egg to the perfect state. Such soils are benefited by burning, or perhaps by the less torrefying operation of charring or half-burning, a process highly recommended by many of our most enlightened horticulturists. This we shall now proceed to notice; but before doing so, we may remark that both burning and charring the soil have been carried to a much greater extent in England than in Scotland, but why, we must leave our readers to speculate.

*Charring* is a process for correcting the tenacity of strong soils, accumulating manure, and converting materials, in themselves next to useless, into excellent fertilisers, such as sawdust, prunings of bushes and hedges, coarse turfy sods, the parings of road-sides, tanners' bark, shavings, and similar vegetable matters. Mr Barnes of Bicton was amongst the first to bring this material before the notice of the gardening public; his mode of operation, therefore, may

be sufficiently explicit. In the "Cottage Gardener," vol. i. p. 83, he thus writes: "To char turfy soil, the best method is to cut it into sods of about a spade's width, and 2 or 3 inches thick, when the soil is not over-saturated with moisture." Summer would, therefore, be the best season, as the sods would be drier; but summer brings with it its own multifarious duties: charring in winter only requires more time, and a greater amount of woody matter to mix with the sods, and cause them to burn. "Burning any kind of material, and allowing it to be consumed, producing nothing but *smoke and ashes*, is a real waste of valuable property, which could be turned to valuable account for the improvement of the soil. To char sods or surface-soil of any kind, proceed by placing a small quantity of combustible stuff—such as dry weeds, shavings, hedge-trimmings, furze, heath, brushwood, or bushes, or any kind of dry vegetable refuse the place produces near at hand; then commence packing the sods, no matter how or what thickness, as any thickness may be charred by placing amongst them, as the heap or kiln is proceeded with, some one of the fore-mentioned materials, or old tan or sawdust, just to keep the materials ignited. It is no matter how large or small the kiln may be formed, for this may be regulated by the convenience of the material at hand, and the quantity of charred materials required;—only, when the kiln is formed, it should be slightly covered or cased with finish earth, to prevent the fire from flaring, and to maintain a steady smouldering, charring, or *roasting*. Much smoke will escape for a time, and when the smoke begins to subside, it is a sign that the materials are charred enough: the fire should then be smothered out by casing up the outside of the kiln quite close to the earth; no large quantity of fuel is required; if too much is employed, it is more likely to consume the sods away into mere smoke and ashes." Charred soil thus produced has been found exceedingly beneficial to many crops; and although, at first sight, the idea of consuming all the organisable matter in the soil subjected to this ordeal seems like reducing it to sterility, yet certain chemical changes are produced which vastly more than make up for this supposed loss. We prefer winter for carrying out such operations, as there is less interruption caused to the general routine, and also because we have a hundred or two of cartloads of useless material to get rid of at all events, such as the pruning of trees, the rotten branches blown down by the autumnal gales, and immense quantities of the thinnings and prunings of banks of evergreens, and the general vegetable rubbish collected over many acres of pleasure-ground.

It follows, therefore, that winter is the most convenient time for this operation. We need hardly remark that the material charred or roasted should be kept dry till wanted for use, and this is easily effected by forming the mass into a conical form, covering it with a foot of garden earth, and then thatching the whole with straw.

Charring or roasting the soil for the destruction of insects is easily effected: after the mass

has been for a day or so in operation, about 3 or 4 inches of the surface upon which crops have grown that have been much injured by insects, along the bottoms of wall fruit-trees, under espaliers, and that under gooseberry bushes and standard fruit-trees, about as far as the branches extend, is carefully scraped off and carried to the charring kiln and thrown upon the mass of ignited matter, mixing with it any combustible material, so that a slow and steady combustion may be maintained. The object of this is to destroy the larvæ of the insects, which take shelter in the soil during winter, as well as to effect that chemical change on the soil itself that the action of fire is known to produce.

*Preparing the ground for the next season's crop.*  
—In all well-regulated culinary gardens, certain systems are acted upon, without which all would become confusion and disorder. One of these is the preparation of the soil, during the previous autumn or winter, so that, when the season of sowing and planting arrives in spring, all is ready for the operation. The expert cultivator has a place for everything, and a thing for every place; and these are so proportioned and arranged that each, as it were, prepares for its successor. In reference to such preparation of the ground, we have the following excellent digest, given by a first-rate practical cultivator in the calendar department of the "Gard. Chron." 1850, p. 808, which is in such perfect accordance with our own views that we shall transcribe it here: "Before the general manuring and trenching of vacant ground, it is necessary to decide on the rotation of crops which are to be cultivated upon it during the ensuing summer, that these operations may be ordered with reference thereto. This arrangement should be made, not for one year only, but for a series or cycle of years. One of the first principles to be attended to is, that no annual crop be grown for two successive years in the same plot of ground. Another variation should be made, by taking care that those crops which immediately succeed each other are not such as are liable to be preyed upon by the same kind of insects, as their increase is encouraged to a fearful extent by thus putting into their way the species of food which they are most fond of. It is important that both the manuring and the depth of the trenching be regulated by the requirements of the crops; and their rotation should be so arranged that the ground be not trenched to the same depth for two successive seasons, but so that different portions of the soil be brought to the surface in turns. The perennial or permanent crops will, of course, form a class of themselves, as they do not require a change of situation for many years; but when this is necessary with any portion of them, the ground from which they are removed will fall into the ordinary rotation in the way of a regular exchange." Confining ourselves, for the present, to the ordinary or annual crops: "By cultivating the celery and cardoon in the Scotch or wide-bed system, a large ridge of soil is thrown up between the trenches, the surface of which is excellently adapted for the cultivation of dwarf pease, beans, spinach, turnips, and similar

vegetables; observing, however, that only the earlier sowings of these several crops should be made on these ridges, that they may be removed in due course before the ground is required for earthing up the principal crop. As a matter of course, this arrangement must not interfere with the very earliest crops of pease, &c., which are generally allowed a place on the side borders near the walls. For the latest crops of pease, &c., a portion of ground must be allotted which, with that occupied by the celery and cardoon ridges, will generally amount to about one-third of the ground occupied with annual vegetables. The extensive turning over which the celery and cardoon soil undergoes, acts admirably in preparing the ground for deep-rooting plants, such as turnips, carrots, onions, &c., and in the following year may be devoted to the cultivation of the cabbage family, whose roots are confined more nearly to the surface. If the vegetable garden is so large as to allow of the cultivation of a portion of the general potato-crop within the walls, it will form a fourth course in the rotation, and will come in after the Brassica tribe. Working upon this system, cabbages have been planted during the autumn on ground which had been occupied by late summer turnips; and the ground which now requires trenching is that from whence the later turnips, onions, carrots, beet, &c., have been removed, and which will next spring be planted with cauliflower, broccoli, &c. Preparation for these should be made by trenching in a very heavy dressing of manure, which shall serve for that and the succeeding crop." To effect this with certainty and satisfaction, a plan of the ground should be made, and the system accurately marked upon it; indeed, without such a plan nothing like correctness of system can be carried out. Such is the preparation of the ground for future crops, as practised in private gardens. The routine of culture and preparing the ground in a market-garden is widely different. "If we take a five-acre piece of ground," says Mr Cuthill, in "Market-Gardening around London,"—"say in November, we find it full of cabbages, which, being planted out about the 25th of October, will be strong healthy plants. The moment these are off, the land is again trenched and cropped with early celery, in well-dunged trenches 6 feet apart, with two or three rows of lettuce or coleworts between them; for market-gardeners do not mould up their celery unless it is very large (often 18 inches high), so there is plenty of time for a crop of coleworts or lettuces to come to maturity. In November, Mr Fitch of Fulham (a very successful grower in a garden of 150 acres) has often upwards of 20 acres of cabbages, every hole and corner, under trees, and all spare places, being full. In March it is again dunged and trenched, and sown with onions; and very often lettuces are planted in the beds, as well as in the alleys. When the onions are off, the ground is trenched and planted with cabbages and coleworts, &c. Next spring a crop of cauliflower, gherkin cucumbers, French beans, or scarlet runners is taken off; but the grand point in the course of rotation is to be continually sowing, and, whatever plants are ready when the ground

is empty, to plant these. The land can well sustain so much cropping on account of the heavy dungings, trenchings, and hoeings which it receives. If you ask a market-gardener what is to succeed this or that crop, the answer is, 'Don't know; it depends on what is ready for planting.' Continued trenching, two spades deep, for any crop, seems expensive; but a strong Irish labourer will turn over from 12 to 14 rods a-day with comparative ease. Market-gardeners know that, after an active crop, the top soil for several inches deep is entirely exhausted, and hence the reason for continual trenching, in order to bring up the top soil that but a few months before had been turned down, with a large proportion of dung to enrich it and fit it for active use, along with the half-decayed manure." Here we have two excellent modes of preparing the ground, but the order of rotation is different. The private gardener has to calculate almost to a day when this or that crop is required to come into use, and must be guided accordingly. The market-gardener is not so tied down; his only care is to see that not a bit of his ground remains empty for a day: he crops it with something, well knowing that the day the crop is fit for use he has a demand for it in the market. By preparing the ground in either way, the maximum of produce may be expected.

#### § 4.—WATERING.

*Watering* is an important operation in gardening, and often very inefficiently performed. Were it always as convenient as it is practicable, we would say that water should not be applied to any plant at a lower temperature than that of the earth that surrounds the roots, because in such cases the roots sustain a sudden chill, and the soil is reduced in temperature to the extent often of suspending growth until it has again become restored to its former heat. This is the case more especially in spring, when the first energies of the plant are being called into action, and when it requires most the aid of heat to increase its excitability. Cold water poured on the roots of plants, even during summer, has a most paralyzing effect for the time, but this is of shorter duration, as the increased heat in the soil counteracts the effects. In autumn it is equally injurious as in spring, because it lowers the temperature at a season when every particle of heat should be allowed to accumulate to maintain the roots in a proper condition during the winter. The application of cold water to plants growing in a high artificial atmosphere is equally injurious; but no excuse can be made why it should not be applied at even several degrees of temperature above that of the atmosphere of the house, and water applied to the foliage under such circumstances should be equal at least to the air in the house. Wall trees suffer much from want of watering over their branches and leaves, and it is probable that one-half at least of all the disasters they suffer arise from a total neglect of this. Evaporation or perspiration must go on more

rapidly in the foliage of trees trained against a wall, from the increased heat by which they are surrounded, than from the foliage of trees growing as open standards. Added to this, a more limited amount of rain falls on such trees, from the position their branches are placed in, and the projection of the copings, than on trees exposed to rain on all sides. We have elsewhere stated that trees derive food from water through their leaves; if, then, wall trees are not syringed, and that often, this supply of food is denied them. Yet how much do we expect from such trees, both in their healthy appearance, and in the size, quantity, and excellence of their fruit. In dry soils, and in seasons of drought, much advantage has been found from watering at the roots also; yet this is seldom thought of, or, if it is, more seldom practised. Water, however, to be useful, must be applied copiously in all out-of-door culture; mere dribblings do more harm than good; and water applied to the roots of plants in the open air, in particular, should be manurial in a slightly diluted form. A few cwts. of guano or pigeons' dung, or other fertilising matter, in the absence of liquid-manure tanks, can easily be incorporated with the water used, and its effects will be sufficiently evident. Watering such crops as celery, cauliflower, asparagus, or such others as require abundance of enrichment, with water unenriched, is next to labour thrown away; and next to this is even enriched water, when not sufficiently largely applied.

The way in which water is applied to even our most common crops is a matter of consideration, so that the quantity used may be applied to the greatest advantage. Now, this cannot be done when it is thrown upon the ground with great force as from the spout, or even very coarsely perforated rose of a watering-pot. In this way it acts much in the way of a thunder-storm shower, battering the ground quite hard, running on the surface, escaping in waste, and, when let fall on young and tender plants, beating them down and half-smothering them with mud. How different, and how much more beneficial, is the gentle evening or morning shower, which falls lightly and equally over the surface! Such we should endeavour to imitate, in the application of water artificially. In light porous soils, heavy showers and heavy waterings have the effect of carrying off, either on the surface or washing downwards, the fertile particles of the soil, leaving the heavy silicious portions behind, and, when long continued, reduces the soil to a state almost of sterility; and were it not for the amount of fertilising matter added to the soil by the fall of genial showers (referred to, p. 18), the rains alone would render the earth almost sterile. It is not, therefore, by the quantity, but by the way in which water is applied, that it is beneficial or injurious to plants. Plants in pots suffer much from careless watering. The soil in a pot, already too moist, is, by the application of more water, rendered water-logged—that is, containing more water than the roots can take up—and, by its occupying the spaces between the particles of soil which should be occupied with air, it actually chokes the plant

for want of that necessary element. This state of matters may readily be detected by feeling the weight of the pot, which will be found much heavier than one of the same size in a proper state as regards water. When the soil around the roots of pot-grown plants is allowed to become too dry, it is not, in such cases, applying water in quantity all at once that is to restore matters to their proper state; it is by giving a little, and repeating that every few minutes, until the whole ball of earth becomes equally restored to its proper state of humidity. Pouring it on in quantity all at once prevents its penetrating through the ball, and causes it to escape between the sides of the ball and the pot, leaving the centre as dry as ever. More plants are killed by injudicious watering than by almost any other point in bad management. In the application of water, to whatever plant or crop, the nearer we imitate nature, the more satisfactory will the results be.

On this subject the following excellent remarks are made by Dr Lindley in "The Theory of Horticulture," p. 125: "When plants are watered naturally, the whole air is saturated with humidity at the same time as the soil is penetrated by the rain; and in this case the aqueous particles mingled with the earth are very gradually introduced into the circulating system, for the moisture in the air prevents a rapid perspiration. Not so when plants in the open air are artificially watered. This operation is usually performed in hot dry weather, and must necessarily be very limited in its effects: it can have little if any influence upon the atmosphere; then the parched air robs the leaves rapidly of their moisture. So long as the latter is abundant, the roots are suddenly and violently excited, and after a short time the exciting cause is suddenly withdrawn by the momentary supply of water being cut off by evaporation, and by filtration through the bibulous substances of which the soil usually consists. Then again, the rapid evaporation from the soil in dry weather has the effect of lowering the temperature of the earth. Such a lowering, from such a cause, does not take place when plants are refreshed by showers, because at that time the dampness of the air prevents evaporation from the soil, just as it prevents perspiration from the leaves. It is therefore doubtful whether artificial watering of plants in the open air is advantageous, unless in particular cases; and most assuredly, if it is done at all, it ought to be much more copious than usual." To the vast utility of copious watering we have the testimony of ages; of which the natural overflowing of the Nile, the irrigation practised artificially in India and China, and other warm countries, as well as the application of water in an enriched state in the melon gardens of Persia, are examples; and wherever irrigation has been carried on upon correct principles, even in the colder climate of Britain, the good effects have been shown. So far, however, as gardens are concerned, the water should be in an enriched state, more especially for annual crops—perennial ones seldom requiring such aid. However much we may recommend

copious watering, or even irrigation, in gardens, one thing is quite obvious, that in most gardens, as at present constructed, little or no provision has been made for securing a supply, and still less for its economical distribution; and therefore, as long as the gardener has his water to carry about in watering-pots, we may expect to see this operation either entirely neglected, or very superficially performed. We have shown how such full supply and proper distribution could be secured (*vide* vol. i., articles WATER, TANKS AND CISTERNS, &c.) There would be no great difficulty even in applying enriched water in a tepid state to our most common crops, thus securing two important points—namely, enrichment in a form ready for the use of plants, and this without lowering the temperature of the soil about the roots; indeed, it might be made to increase it.

From all this it will be seen that watering in the open air is of sufficient advantage, if properly applied; but even in our present advanced state of horticultural science, we seem to have little control over it. With plants in glass-houses the case is different, and there a more correct system may be pursued. There are two conditions in the existence of plants that, as concerns watering, are widely different; those are, the season when they are at rest, and that when they are in the vigour of growth. In the former state they require but little water, because they lose little by perspiration, and hence the draught upon the root for food is greatly diminished; while in the latter case they require an abundant supply, on account of the increasing perspiration, which begins to take place as soon as the plant is excited, and increases as the foliage develops itself. During the younger state of the leaves, their draughts on the roots are most powerful, on account of their perspiratory action being most rapid at that stage, which points out to us the necessity of watering abundantly, and affording them all the light in our power. This supply should be gradually diminished as the tree or plant arrives at a full development of its parts, be the object of their cultivation fruit, flowers, or wood; the only exceptions being oleraceous annuals. Watering while the fruit is arriving at maturity tends, no doubt, to increase its size, but this is obtained at the sacrifice of a great amount of its flavour; and watering when the wood is about nearly formed, causes it to continue growing till too late a period of the season; and, as a consequence arising from its increased size, and the quantity of fluid contained within it, it is prevented from ripening, and is therefore liable to be killed by the frosts of winter.

Plants with large leaves require more water than those having smaller ones; and hence in nature it will be observed, that many aquatic plants, and those growing by the banks of rivers and lakes, have leaves above the ordinary size. It may be taken, however, for granted, that such plants as the *Victoria regia*, the *Nelumbium*, *Nymphæas*, &c., have extraordinary perspiratory power on account of the very large size of their leaves; and to aid them in decomposing the fluid they absorb, a high temperature and bright sun

are necessary. The melon and the cucumber, although by no means aquatic, having large leaves, perspire enormously, and hence require a very large supply of water, if placed in a high temperature; but in a low temperature, and equally watered, gum, canker, and spot take place, and ultimately death—the heat not being sufficient to decompose the water taken up by their roots. Plants in metallic hot-houses, when glazed with large panes of glass, require much more water than plants of the same species grown in houses with small glass, and much crowded with astragals and rafters. Practically, plants in pots or tubs should be watered often, and not too much given at a time. If water be given in large quantities, it passes through the soil in the pot, provided it be properly supplied with drainage, carrying with it much of the richness of the soil; and if imperfectly drained, causing the soil to become water-logged, cold, and impervious to the air, so necessary to the welfare of the roots.

Watering is the mainstay of gardening in warm climates; it is particularly so in artificially-heated climates, and by no means to be disregarded even in our naturally cold and humid country. The utility of watering newly-planted trees, shrubs, and plants is admitted, but the proper application of it little understood. Many conceive that the water for their plants, like what they use themselves, cannot be too fresh and cold. Than this, a greater mistake does not occur in the whole art horticultural. Rain water is best of all; and dirty stagnant water, and at a high temperature, the most congenial to the plants. Cold spring water is the worst of all. It is not going too far to say, that pure water should seldom or never be applied, but that it should be impregnated with some enriching matter, of which our modern artificial manures offer abundant choice. Those who have found, if they have bestowed a passing thought on the matter, how little service their continued watering has done to their plants in a dry summer, would do well to think of this.

The fertilising matter conveyed to the soil by rain water, compared with spring water, must exercise a most important and beneficial influence on plants. The researches of M. Barral, of Paris, show that, in six months, the rain which fell upon an area, equal in extent to one English acre, contained, as near as possible,

7.75	lb. of ammonia.
36.50	— nitric acid.
5.56	— chlorine.
12.60	— lime.
4.81	— magnesia.

A writer in the "Critic," referring to M. Barral's experiments and statement above, says, "From July to December is usually the drier half of the year, as well as that in which the less fuel is consumed, so that we may safely double these quantities in estimating the annual supply per acre of nitrogenous compounds gradually distributed over a country by the rain. For the sake of illustration, I have calculated the amount of the solid constituents of the rain falling on an area equal in extent to Great Britain; and, balancing the various causes likely to lessen or

to increase the quantity of these matters which would so fall on this island, we may venture to set the one against the other, and apply the above statement to our own country, as the basis of an estimate which singularly manifests the 'power of littles,' as well as the grand scale on which even the minutest of natural phenomena proceed. Thus, on the Parisian data, the weights of these fertilising materials, annually supplied to the soil of this island by the rain, amount to about

400,000	tons of ammonia.
1,850,000	— nitric acid.
279,000	— chlorine.
640,000	— lime.
244,000	— magnesia."

It is probable no other water in a natural state contains so great an amount of fertilising matter; and it is quite certain that the waters of many springs, should they peradventure contain no material injurious to vegetation, contain little or no matter which can properly be called the food of plants. It therefore is a matter of the deepest importance to the horticulturist to endeavour to secure rain water; and this is by no means so difficult a matter, if properly gone about.—(Vide sect. TANKS, &c.) Next to rain water is that which is, by chemical analysis, proved to contain the largest portions of the above constituents, and the least amount of those matters which are either useless or injurious to vegetation. Those who have to depend on springs for their supply of water for garden purposes, had need ascertain the chemical properties of them before going to the expense of forming wells, pumping the water up, or bringing it from a distance; for as the water may be deficient in the above matters, so is their labour in vain, and the expense incurred next to thrown away. Plants require something more than pure water. It is the quality and not the quantity of water that is beneficial to them. Some interesting experiments have recently been made by Chevandier and Salvétat, to solve the problem, whether it is the quantity of water applied or put in motion, or the presence of matter held in solution—which water, acting as a vehicle, conveys to the roots of plants—that is of greatest benefit to them. In carrying out their experiments, the water of two different springs was made use of, which, for clearness, we shall call No. 1 and No. 2. 255,744 cubic metres of water,

No. 1, was applied per hectare, and 164,281 cubic metres from No. 2, to the same extent of surface. The produce in the first case was 2312 kilogrammes per hectare, while in the other it was 7896 kilogrammes. The second year's experiments produced the following results: 126,273 cubic metres were applied per hectare from spring No. 1; and the weight of crop produced was 2749 kilogrammes. 130,311 cubic metres from No. 2 produced, in weight of crop, 10,469 kilogrammes. "We thus see," say these gentlemen, "that with equal quantities of water, and in conditions in other respects perfectly comparable, or even with larger quantities of water from the bad spring (No. 1), the crop of the meadow watered by this spring has only been one-third or one-fourth of the crop produced under the influence of the water from the good spring (No. 2). It is then in the *quality* of the waters, and not in their quantity, that we should seek for the causes of these very considerable differences in the crops."

The gases and organic matters held in suspension in both these springs were nearly the same. Messrs Chevandier and Salvétat therefore sought the solution of the problem in the organic matters dissolved in these waters. According to the centesimal composition of these matters in the springs No. 1 and No. 2, taken as types in this extract, oxygen and hydrogen were found in the same proportion; but these matters were more rich in carbon in spring No. 1, and more rich in nitrogen in spring No. 2. The nitrogen in No. 2 was to that of No. 1 as 100 to 42, whilst the carbon in No. 2 was to that of No. 1 as 100 to 94. The two propositions here laid down do not sufficiently explain the different fertilising powers; but the following will do so: "If instead," say these gentlemen, "of considering merely the absolute quantities, either of organic matters or of nitrogen contained in these matters, we seek the relative proportions of the nitrogen and carbon which enter into their composition, we find that 100 of carbon correspond in the good spring to at least 11 of nitrogen, and, for the bad spring, to 4 of nitrogen at the most; whence we see, that the fertilising properties of our good springs correspond completely to a proportion three times stronger, considered relatively to the carbon."—(Vide *The Chemist*, and *Comptes Rendus* of Feb. 1852.)

## CHAPTER XIII.

### MANURES.

#### § 1.—KINDS OF THEM, ETC.

VARIOUS materials, under the general denomination of manures, have from the earliest ages been applied to the soil, with a view to increase its fertility, or, in other words, to supply plants with those elements necessary for their healthy development, in which the soil may be either naturally deficient, or which have been extracted from it by previous crops. Hence the great importance of ascertaining, first, what elements the soil is really deficient in; and, next, what the material added contains necessary for the crop to be reared. All plants do not require the same food, and hence, without a knowledge of these important facts, very useless, if not injurious additions, may possibly be made. It is to arrive at a correct conclusion as to this, that the chemistry of soils and of plants, as well as a practical knowledge of their various natures, is of so much importance; and without some knowledge of this, all manurial applications whatever must be regarded with suspicion as to the effects they will produce.

Manures are usually divided into two classes—viz., organic and inorganic; but more naturally into three—namely, animal, vegetable, and mineral. The first of these comprehends those substances that are derived from animals, either in the shape of excrements or from their dead bodies; the second includes the vegetables so applied, either singly or mixed; while the third is composed of minerals, fossils, earths, or earthy substances, either applied in their natural state, calcined, or otherwise reduced in form, or mixed with other materials. Organic manures consist of carbon, hydrogen, and nitrogen, and are undoubtedly the most valuable. Inorganic manures, or the substances employed as such, are very numerous, but the mode in which they act is still very imperfectly understood. Were they as important as some would lead us to believe, they of all others would be the most valuable to the horticulturist, on account of the convenience of their application. Considerable difference of opinion exists as to organic or inorganic matter being the best fertiliser of the soil, Mr Lawes, and with him the majority of practical experimenters, contending for the former, while Liebig, heading the chemical host, as strongly advocates the latter. We are inclined to follow

the former, so far as the principal supply of the food of plants is concerned, and admit the theory of the latter only in so far as a proportion of certain mineral matters is necessary for the proper action of the organic matter in its preparation as the food of plants, when reduced to an aqueous or gaseous state; and also that certain minerals enter into the structure of plants, giving them greater strength of stem, and thereby enabling them better to maintain an upright position—a position of all others the most favourable for the action of atmospheric influences upon their respective organs. The real object of a plant is to reproduce its kind, and when it has done so, as in the case of annuals, it ceases to live—decomposes, and becomes resolved into that matter upon which it had existed, and becomes the food of plants of its own, or probably of other species. The decay of the annual parts of plants, such as their leaves, &c., in the case of trees, and the higher grades of vegetable life, aids the nourishment of themselves while in life, and fertilises the soil after their removal for other crops. Such is the natural production of organic manure. On the other hand, the advocates for mineral or inorganic manures say: Plants, by means of their roots and leaves, perform the various functions necessary for their existence; the former penetrate the soil in search of moisture, and of mineral ingredients dissolved in moisture, and essential to the plant; and these materials are taken up by the sap and passed into the leaves, where, by the influence of the sun, the leaves acquire the power of acting on various gases contained in the atmosphere, of absorbing them, and of changing them into materials adapted to their growth. Without the mineral ingredients from the soil, plants could not obtain them otherwise, as none exists in the air. "If we consider," says Mr Nesbit, in "Lectures on Agricultural Chemistry," "the nature of plants, in their wild state especially, we shall find, if they be supplied with an adequate quantity of mineral matter according to their varieties, and according to their circumstances, they will obtain all the rest from the air without any assistance." Mr Nesbit appears to overlook the amount of nourishment plants, even in their natural state, derive from the decomposed remains of their predecessors.

No doubt, all plants derive a great part of

their food from the atmosphere; and the lower they are in the scale of creation, the more evident this appears. The first traces of vegetation on the cooled-down masses of lava in volcanic regions are various species of cryptogamic plants, which have scarcely such appendages as roots; there, however, they thrive, deriving their whole sustenance from the atmosphere: by their dissolution they leave organic matter in the fissures, which, in turn, supports a higher order of vegetation to perform the same important office, until a sufficient body is at last accumulated to give support to the largest shrubs and trees; thus showing, as we rise in the scale of vegetable life, the vast importance—nay, the positive necessity—of organic matter being present to secure healthy development. The operation of rendering the most sterile soils in course of time fertile, may be instanced in the case of planting with trees soils naturally possessed of little or no organic matter; yet on such soils do trees not only grow, but in time produce thousands of tons of valuable timber, leaving the soil much richer in vegetable matter than it was prior to their being planted. During the first few years, trees so circumstanced make little progress; but as they increase in size, and as their annual exfoliation increases, so do they in bulk and magnitude. These facts are quite sufficient to prove that vegetables have the power of feeding largely on the atmosphere, and deriving from it the great bulk of their sustenance. According to some, more than three-fourths of the solid matter found in plants is derived from the air, and not from the soil. Seeing, therefore, that plants derive so much of their food from the air, it may not be unimportant to inquire from whence and how their food is provided. We believe that it arises from the soil in the shape of gaseous matter disengaged by the great chemical operations constantly going on in the great laboratory of nature, and mixing in the atmosphere, and fed upon by the leaves of plants. The supply necessary to keep up this enormous demand is almost provided by plants themselves, even when in a state of nature, by the annual shedding of their foliage and decaying parts; but when in an artificial state, where greater development is required, then it becomes necessary for man to add to these sources such materials, or what are called manures, as he deems best fitted for their wants and circumstances.

Before noticing those manures individually, which experience has proved to be of most consequence to the horticulturist, we may observe that, according to our highest authorities on vegetable chemistry, all plants are composed of oxygen, hydrogen, carbon, and nitrogen, or azote, with a small proportion of saline bodies. All manures, therefore, should include these elements, as a deficiency of either may prevent the formation of those parts in the vegetable, for which its peculiar organisation is contrived, and on which much of its healthy existence depends.

All manures must be rendered soluble, as no solid substance can enter into a plant. Hence, manures deposited in the soil must undergo a species of dissolution, and become watery or

gaseous before they are capable of being absorbed either by the roots or leaves of plants. Sir H. Davy thought that such parts as became gaseous, and passed into the atmosphere, afforded little benefit to plants, as the gases soon become diffused through the mass of surrounding air. More recent authorities think otherwise, and say that plants feed as much by the leaves as by the roots, and that their food is supplied by the gases which evolve around them, and which of necessity must arise from the soil.

The application of manure to the soil no doubt acts in two very different ways, yet both indispensable to vegetable existence; first, by being taken up by the roots, after it has assumed an aqueous form; and, secondly, by being taken up by the leaves, when it becomes resolved into a gaseous state. The first of these has been long admitted, the other has more recently been recognised. To insure that effect in the former, the manure is buried in the soil near to where the roots are situated. To secure the latter, it may be thought that the manure should be spread upon the surface, or probably applied to the leaves in a more direct manner. Neither of these are absolutely necessary, although of the effect there can be little doubt. A certain portion of the manure, when reduced to a proper state, is taken up by the spongioles at the termination of the roots, while another portion, becoming disengaged from the soil, escapes into the air which surrounds the plant, and is fed upon by the leaves. Hence one of the great advantages of frequently stirring the soil between rows of crops, and which is done by most people for the suppression of weeds; by others, as they say, to promote evaporation, and for the admission of the rays of heat to the roots—few thinking that this very necessary operation tends to facilitate the escape of fertilising gases from the soil, to be fed upon by the leaves, which would be prevented from escaping if the surface was allowed to remain hard and unbroken. No doubt, a great amount of these gases is dissipated into the atmosphere, and may be lost; or they may be returned, for aught we know, by various atmospheric operations—such as becoming mixed with rain, dew, &c., and in this state be brought to act upon the foliage in a way unknown to man. Nor is it necessary that these gases should become amalgamated with either rain or dew; they may remain in a gaseous form, and be carried to the foliage, if not of the plant from under which they arose, of others equally important, by the action of the air itself. The effects of gaseous food taken up by the leaves must of course be much less apparent in the open air than it is within the more limited atmospheres of pits and hot-houses; and that they are actually less is admitted. The principle, however, remains the same. The heat and moisture afforded by the tank system of heating is, so far as these two elements go, quite satisfactory; but plants do not thrive, by any means, so well in houses so heated, as in others heated by the use of stable manure in a state of fermentation; nor do plants, in pits heated by leaves, tanners' bark, flax refuse, or any

other vegetable matter subjected to the same amount of fermentation, either prosper so well, or recover from a sickly state so soon as they do in pits heated by stable manure, all other conditions being the same. Practically we know this, and account for the difference in the almost total absence of ammoniacal gases, or other fertilising matter, in the former when compared with the latter. So apparent is this, that some of our best cultivators—Mr Fleming of Trentham, for example—have recommended pigeons' dung, or other highly-enriched manures, to be mixed with the water in the tanks, to bring about this invigorating state in the atmosphere of pine-stoves, which are deficient in it—although heat and moisture are abundantly supplied by the tanks. Sickly plants, *in pots*, plunged in a common dung-bed, rapidly recover; and pines grown in such material, although their roots are also confined *within pots*, attain a larger size and greater vigour. Melons grown in pots suspended by their rims, and placed over a vault heated by dung linings, are found to prosper as well as when planted in soil laid immediately over the hot-bed. These and many other instances could be given of the healthy condition of plants, when grown in an atmosphere highly charged with gases arising from dung in a state of fermentation, and while their roots are almost precluded from being affected by them. That the plants so circumstanced must derive no ordinary share of their nourishment in a gaseous form is pretty evident, and it is equally so that that nourishment is not conveyed to them by their roots. It follows, therefore, that the leaves are the organs through which it is supplied. If, therefore, such an operation goes on in pits and hot-houses, it necessarily follows that the same action is going on in the open air—with this difference only, that, in the former case, the atmosphere is more limited and the supply more abundant than in the latter. These effects have been discovered and accounted for by men of observation and intelligence—such as those who practise in the highest grades of artificial cultivation; while the more superficial go-by-rote practitioners scarcely bestow a thought upon the matter.

Absorption by the root is the process by which plants take up their food from the soil, or from those ingredients which are artificially added to it, called manures. The investigations of Hedwig and Decandolle have long ago set this matter at rest, at least to the satisfaction of vegetable physiologists. For the satisfaction of others, we may state that the food of all vegetables must be reduced, by some means or other, to an aqueous form, and in that state it is absorbed by the spongioles, or sponge-like appendages situated at the points of the fine fibres or root-terminators, and from them conveyed through the roots to the stem, branches, and leaves of the plant.

Absorption by the leaves was first elucidated by Duhamel and Marriotte, and by the experiments made soon afterwards by M. Bonnet of Geneva, chiefly with a view to ascertain whether the absorbing power was alike on both surfaces

of the leaf. The deductions drawn by him were, that the leaves of herbs absorb moisture chiefly by the upper surface, and the leaves of trees by the under surface. The cause of this disparity between the absorbing surfaces of the leaves of trees and herbs was not very clearly shown by Bonnet. Keith conjectures that the physical cause might be the existence of a greater or smaller number of pores in the leaves of the herb and tree respectively. The chemical cause would be the peculiar degree of affinity existing between the absorbing organs and the fluid absorbed. Duhamel, looking to the physical cause merely, regarded the lower surface of the leaf of the tree as being endowed with the greater capacity of absorbing moisture, chiefly for the purpose of catching the ascending exhalations which must necessarily come in contact with it as they rise, but which might possibly have escaped it if absorbable only by the upper surface, owing to the increased rapidity of their ascent at an increased elevation; and regarded the upper surface of the leaf of the herb as being endowed with the greater absorbing power, owing to its low stature, and to the slow ascent of exhalations near the earth. "This," says Keith, "does not throw much light upon the subject; and the experiments were still deemed insufficient, as not representing to us the actual phenomena of vegetation, though the fact of the absorption of moisture by the surface of the leaf is fully confirmed by such phenomena." The leaves absorb both moisture and gaseous food by means of the stomata, or, in the absence of pores or stomata, by means of the absorbent power of the epidermis, not only of the root and leaf, but often, as it may be believed, by the other parts of the plant also—at least when they are soft and fleshy, as must be the case in succulent plants, which are for the most part devoid of leaves altogether.

## § 2.—ORGANIC MANURES.

*Stable-yard manure.*—The most important, and hence the most general in use of these, is stable-yard manure, composed of vegetable matter, such as straw, hay, and other material employed either as food or litter to such animals as the ox, the horse, the cow, the hog, &c. It is valued in proportion to the quantity of their excrements mixed with it, the amount of urine with which it is saturated, and the manner in which it is kept previous to its application to the soil. The quality of the food, and the peculiar construction of the digestive organs of the animal, affect it also in some degree; and hence the dung of one animal is of higher value than that of others. "For," as Donaldson (*On Soils and Manures*) remarks, "the same kind of food given to animals of a different genus will yield an excrement of a very different quality; and even when given to those of the same species, and under the same treatment, a great difference will often be found, which can only be attributed to the construction and action of the constitutional organs. The dung of swine is of a cold nature, inclining to form a saponaceous

mass, and constitutes a manure of great power and duration. The dung of cattle contains matter soluble in water, and gives in fermentation nearly the same products as vegetables, absorbing oxygen, and producing carbonic acid gas. The insoluble part seems to be mere woody fibre, and analogous to the residuum of the vegetables that constitute their food, after being deprived of all the soluble materials. The process of rumination imparts a richness of quality from the juices of the saliva, necessary for, and produced by, the additional chewing which the food undergoes." The great value "of stable-yard manure arises from its containing both animal and vegetable substances; the former abounding with molecules of the body itself from fatty matters, the latter yielding an aliment to plants from saccharine and extractive matters, but exerting no action on the soil or its contents; the former possessing substances more active and energetic, which also afford a direct aliment, and act on the vegetable matters, and decompose and stimulate the humus in the soil, which becomes exhausted by supplying the extractive matter and carbonic acid, and requires a regular renovation." As regards the state in which the nutritive matter of stable-yard manure should be, to be at once ready to enter into the composition of plants as an aliment of food, there can be but one opinion—it must be aqueous or gaseous; and hence recently-applied manure, in a solid state, can be of no use to them until it is reduced to a state of solution and suspension. Water is the vehicle by which fertilising matters are conveyed to the plant, and these must be in a very comminuted state to be capable of being suspended in it. "Chemists are much divided," Dr Madden observes, "as to what precise amount of decomposition is requisite to render organic matter in a proper state to become food for plants. All agree that decomposition must have commenced; some maintain that it must be completed. My own belief, founded on extensive observations, and not a few experiments, is, that all the products of decomposition, in every stage, are available as food for plants, provided they are either liquid, or capable of dissolving in water." In reference to applying manure to the soil immediately before planting or sowing, Mr Donaldson very justly observes, "A mass of dung, cold or warm, lying in a drill, must be in too gross a form to present and afford ready and palatable aliment to the tender fibres of plants, and a further reduction and mixing is necessary to produce that matrix of comminuted and finely-blended substances in which plants delight so very much to grow. The influence of air and moisture will reduce dry substances to a manure by blending with the soil. Much time, however, is required, and a great quantity of moisture, and frequent stirring of the land. It is reasonable to suppose that stable-yard dung, and all substances that are applied to land as manure, should be in a reduced state; and in the case of the former, it would require an application to the land at an early season, that it may be broken and mixed by the subsequent working of the implements;" or, in other words, that it may be changed and

rendered soluble by the time the plants require its assistance. The best compost-heap is the soil itself, and the best system of manure management is to bury it in the soil before it loses any of its fertilising properties. The changes necessary for its reduction to a proper food-supplying state will take place better in the soil than in the exposed midden. Of all manures, stable or farmyard dung is the most effective fertiliser yet known; and although others may be equally quick in their effects, yet none of them are so lasting. Compared with inorganic fertilisers, and many of the modern artificial compounds, it may be set down as the real substantial food of plants; while they can only be regarded as provocatives of appetite—mere stimulants, producing a sudden and ephemeral effect—leaving the plant much in the condition of an animal pampered with rich food in youth, and left to shift for itself before it has arrived at a state of puberty—that is, the period of existence, in both animals and vegetables, when they require the greatest amount of nourishment.

Notwithstanding the vast importance of this material as a fertiliser, few things within the whole range of rural economy are so shamefully wasted and misused. Unnecessary exposure to the weather, excessive fermentation, and a slovenly or ill-timed application of it to the soil, are of every-day occurrence. To avoid these (the two former in particular, for it is in these states that the greatest loss is sustained), the manure should be committed to the soil as soon after it is made as convenient, and the process of fermentation and decomposition allowed to go on there. Gardens are differently circumstanced in this respect from farms; because, in the former, crop after crop succeeds each other in such rapid succession, that almost daily, if not weekly, opportunities offer of ground being cleared of one crop, and under preparation for another. These opportunities should not be lost sight of; and as garden ground can hardly be too much enriched, manure in greater or less quantity should be applied to almost every crop. By this means the ground becomes enriched by the very essence of the manure, which would otherwise be allowed to escape in a gaseous state during excessive fermentation, deprived of much of its best properties while undergoing unnecessary decomposition, whether on the dunghill or cucumber-bed, leaving it at last, when in the form of what is called spit dung, so highly prized by some gardeners, in a state little better than that of a mass of inert peaty matter.

The application of stable-manure, for the most part, has hitherto been considered as beneficial only when applied immediately previous to the sowing or planting of the crop. To this long-received opinion we by no means subscribe, and therefore in practice apply such manure generally in autumn, through the winter, or, indeed, whenever the ground requiring enrichment is cleared of its crop. This is new neither in theory nor in practice; it has been acted upon by excellent cultivators with the best results, and was first recommended by Sir Humphry Davy, who has clearly enough explained the principle in his papers on "Agricultural Chemistry." When

the manure is used in a fresh state, and dug into the ground in autumn or during winter, the soil has sufficient time to become completely impregnated with the elements of fertility required for the succeeding spring crop; at sowing or planting, a slight dressing of guano, bone-dust, nitrate of soda, &c., is given, to act as stimulants in furthering the early growth of the crop; as the roots descend into the soil, they come into immediate contact with the store of food previously buried in it, and now reduced to that state in which only it can be serviceable for the purpose of nutrition. Much of the fertilising properties of manure is lost by over fermentation, the effects of rain, snow, and exposure to the weather; and by the time the process, as generally followed, of turning, fermenting, and preparing the dung, has been accomplished, little of its best properties is left; whereas, when the manure is applied to the ground soon after it is made, and dug in, a slow process of fermentation takes place, during which the ammonia is absorbed by the alumina as fast as it is formed. This will be found to be more strikingly the case in strong soils than in light ones, as the former contain a greater portion of alumina and humus than the latter; besides which, a mechanical improvement takes place during the decomposition of the littering matter, it keeping the soil open and more pervious to air. Another advantage attends autumn or winter manuring; namely, it is more convenient to bring the manure in then than during summer, when the process of carting or wheeling would be destructive to the walks. And as garden ground can scarcely be rendered too rich, it matters not how long before the crop is to be sown or planted the manure is applied, as it is enriching the soil all the while, and fitting it for cropping when the time for so doing arrives. Stable-yard manure loses more than is generally imagined by the process of making, as usually performed. Direct experiments have shown, as stated in Morton's "Cyclopaedia of Agriculture," that "100 cwt. of fresh farmyard manure are reduced to 80 cwt., if allowed to lie till the straw is half-rotten; 100 cwt. of fresh farmyard manure are reduced to 60 cwt., if allowed to ferment until it becomes 'fat and cheesy;' 100 cwt. of fresh farmyard manure are reduced to 40 or 50 cwt., if completely decomposed. This loss not only affects the water, and other less valuable constituents of farmyard manure, but also its most fertilising ingredient, nitrogen. Chemical analyses have shown that 100 cwt. of common farmyard manure contain about 40 lb. of nitrogen; and that, by fermentation during the first period, 5 lb. of nitrogen is dissipated in the form of the volatile ammonia; in the second, 10 lb.; in the third, 20 lb. Completely decomposed manure has thus lost about one-half of its most valuable constituent. The practical deduction which appears to be warranted by these experiments is, where it is possible, to apply farmyard manure in a fresh state to the land." Rank and entirely unfermented manure may be less valuable to thin light soils than to strong heavy ones, but even much of this depends on the kind of crop which is immediately to follow. Our own experience

satisfies us as to the advantage of manuring at these times, and in this way, and we have only to look to the highest cultivated garden-ground in Britain, the London market-gardens, for a corroboration of the fact. They lay on the manure as they receive it, not with a view so much to benefit the succeeding crop, as to keep the ground in a high state of enrichment for all succeeding ones, the manure undergoing all the while the necessary changes from a solid to a soluble state.

*Green vegetable manure* is an important and much-neglected fertiliser in garden culture. It requires no previous preparation: all plants contain much saccharine or mucilaginous matter, and therefore cannot be used too soon after their death. Green vegetable manure consists of the sweepings of lawns, annual weeds before they have formed their seed, pond weeds, fresh turf, the refuse of vegetable crops, &c. A great waste occurs in most gardens by carrying all refuse vegetable matter to the rot-heap, there to decompose and be returned again in the shape of vegetable mould, while no small portion of it is sent down the nearest river, or buried in the most convenient pit. In its application it should not be buried to too great a depth, otherwise the necessary fermentation would be prevented by compression. At a proper depth decomposition proceeds slowly, the soluble matters are gradually dissolved, and the slight fermentation that goes on, checked by want of a free communication with the air, tends to render the woody fibre soluble, without occasioning the rapid dissipation of elastic matter. The use of green vegetable manure is of the greatest antiquity; it was practised by the ancient Romans, and still largely employed in Italy to this day. It is probable, however, that this mode of enriching the soil is better adapted to warm climates than to colder ones, because vegetation is more rapid and luxuriant in the former than in the latter. This opinion, sound or unsound, bears lightly on gardens, where the climate is supposed to be warmer, and the crops far more luxuriant than on farms. We think highly of green vegetable manures; and, operating upon a light soil and good climate, we commit all such matter not eaten by animals to the soil, and indeed grow spinach, spurrey, and buck-wheat, and other rapid-growing crops, for the express purpose of being dug into the ground immediately before the formation of their seed.

*Sea-weed* ranks amongst green vegetable manures, and its application as such in places where it abounds is so far commendable. It abounds in soda, or the mixed mineral alkali, and contains somewhere about  $\frac{1}{8}$ th of a gelatinous substance similar to mucilage, and  $\frac{1}{3}$ ths of its weight of water, but no ammonia. Like all green vegetable manures, it should be applied to the land as soon as gathered, as it loses both bulk and quality by keeping. Its effect on land is transient; and it is probable that, if the expense of collecting and applying were expended on the purchase of salt, applied in rainy weather, the effects would be equal.

*Rape-cake* contains carbon and hydrogen, and hence is an effective manure, better fitted, how-

ever, for damp soils than for light and sandy ones. Applied as manure, it has been found destructive to that intolerable pest the wire-worm (*vide* p. 182). The rate at which it is applied is about 5 cwt. per acre.

*Leaves of trees.*—These, from necessity, are collected during autumn and winter in large quantities where extensive pleasure-grounds exist, and, when rotted down, afford an excellent manure for most soils. Leaves of trees, when decayed, as well as the wood itself when so reduced, form what is termed vegetable mould, containing more charcoal but less oxygen, weight for weight, than the plants that produced it. It yields more ammonia, and contains more azote, on account of the different circumstances under which it has been formed. Vegetable mould is an indispensable manure in garden culture.

*Tanners' bark.*—Both bark and leaves of trees, according to Donaldson (in "Treatise on Soils and Manures," p. 15), "require long time, and much mixing and preparation, to reduce them to mould: hot lime will be the quickest solvent for fresh bark, and the destruction of the fibre being effected, earths and dung may be added, which will bring the whole mass into a soluble and putrescent state. Hot stable-dung has been used in the first application, in order to reduce the woody fibre; but caustic lime is stronger and quicker, and, after the dissolution has been effected, the mild materials may be added, and the mixture completed. Time will effect a dissolution of the fibre without any mixture with the bark; but a long period will elapse, and it is usually preferred to break it up by hot applications. The reduced mixture may be used as a manure for any purpose, but chiefly for top-dressings, arising from its finely divided and comminuted state." With decayed leaves and a copious admixture of sharp sand, it makes an excellent compost for growing American plants in, many of which, particularly azaleas and rhododendrons, thrive as well in it as in natural peat-earth. It is a good manure to light sandy soils deficient in vegetable matter, and, in a less decomposed state, valuable for keeping open soils of the closest texture.

*Sawdust* is much of the nature of tanners' bark; but, unless entirely of oak wood, it contains much less of the tannin principle, that of coniferous trees containing a considerable amount of resinous matter; but when both are extracted, it forms with sand a good substitute for peat, for hardy shrubs and trees. Both, however, should be broken down without the use of caustic lime, when intended for such purposes, as all American plants have a dislike to calcareous matter even in small quantities. Both tanners' bark and sawdust, when charred, constitute a tolerable manure, and are both in that state valuable, when incorporated with nightsoil, urine, and similar potent manures.

*Horns and hoofs* of animals are similar in constitution, containing very little earthy matter, and only 0.023 of phosphate of lime; the chips and shavings of both, procured of the comb-makers and turners, have been strongly recommended by some. Repeated trials have not led us to a like conclusion.

*Oyster shells*, like those of both sea and fresh-water animals, are constituted chiefly of carbonate of lime combined with soft animal matter; they differ chiefly from animal bones in having a much greater proportion of carbonate of lime, affording sometimes almost pure lime when burned.

*Bones ground to powder* are extensively used in stimulating the first efforts of vegetable life, being sown immediately before, or along with, the seed. In a crushed state they are employed in the formation of vine borders, as they are slow in decomposing, and, in their decay, afford food to the plants long after all other manures applied at the same time have become exhausted. We have found them excellent as drainage for plants intended to be kept long in the same pot. The action of bone-dust upon the soil appears to be little understood. "Up to a certain quantity used," Mr Stephens remarks, "this manure has an evidently beneficial effect, but beyond that quantity no apparent benefit is derived from its use, in so far, at least, as the crop is concerned. I have tried to raise turnips," he says, "with different quantities of bone-dust, varying from 12, 16, 20, to 24 bushels per acre, and found the crop improved up to 16 bushels; but the quantities beyond that, even to 24 bushels, produced no greater effect on the crop in the same field, and on the same sort of soil, than 16 bushels. It is therefore unnecessary," he concludes, "in so far as the crop of turnips is concerned" (that being the crop he experimented upon), "to sow more than 16 bushels of bone-dust alone, or 8 bushels with coal-ashes or street manure." Where the ground has been previously manured with farmyard dung, 8 bushels of bone-dust is deemed amply sufficient for any annual crop. Bone-dust, in combination with sulphuric acid, has of late years been greatly recommended, and in this state it has been found to have greater effect in raising crops on strong land than bone-dust alone. The manner of preparing the sulphurated bones is to mix a given quantity of sulphuric acid with twice its bulk of water, and to place twice the weight of bone-dust as of the acid in a tub or trough, and pour over the bones the prepared liquid gradually, and by times; the bones will become entirely dissolved, and form a mass with the acid and water. When the mass is dried, it will assume the appearance of granulated powder, and is then fit for use. One cwt. of bones, with 56 lb. of sulphuric acid, will be sufficient bone-manure for an acre of strong garden-ground, previously manured with stable-dung; for it should never be overlooked that bone-dust, like most others of the modern fertilisers, should only be regarded as an auxiliary, and not as a general manure. Bones are often broken down by fermentation with sifted coal-ashes, and even with pure sand, and their value considerably increased, probably on account of their being disintegrated to the smallest possible degree, and thereby mixing more readily with the soil. The method of fermenting bone-dust in this manner is thus described by Mr Stephens: "Mix four cart-loads of bones with as many of sand, or mould, or sawdust, in a flat-topped heap. The bones should be thoroughly drenched with

water, and the other materials moistened. In a few days such a heat will be generated in the heap as to render it unbearable by the hand. As the wet side of the heap will not be heated so much, it should be covered with sand. Whether the heat should be allowed to die out before the heap is used is a point still unascertained, but a large heap makes better manure than a small one; so do unboiled bones and fresh ones than boiled and stale ones. Large bones may be reduced by fermentation in this way, by turning the heap over at the end of a fortnight and watering it afresh, and at the end of a month very few whole bones will remain." This is important to those living remote from bone-mills, and might be taken advantage of where dog-kennels are maintained, for the preparation of the bones of dead carcasses used for the dogs' food.

*Blood* is a powerful manure, and has been beneficially applied to fruit trees, particularly the mulberry and vine. In general, it is formed into a compost with earthy or vegetable matter.

*Animal bodies.*—Of all manures, animal substances, when well prepared, are the most powerful promoters of vegetation. "In that state," Mr Donaldson remarks, "almost the whole body becomes volatile, and so far attenuated, subtilised, and refined, as to be rendered capable of entering the vessels of the minutest plants. So soon as the parts are sufficiently divided to be mixed with the earthy materials, the process of preparation must go on quickly; and as soon as incorporation has been effected, the application must not be long delayed, in order to prevent the great loss of bulk that will ensue from the rapid decay of the many complex elementary substances which compose the organisation of the bodies." A few years ago, Mr Roberts, author of an excellent treatise on the vine, brought the use of carrion, or animal manures, before the notice of the public, and employed it largely in the preparation of fruit-tree borders. Of its advantages as a powerful fertiliser there can be no doubt. There is, however, something loathsome in the application. When formed into a compost, slaked lime may be mixed with the heap just before it is to be used, and, by combining with the other ingredients, will quicken their action, and add a soapy and very valuable quality to the compost.

*The dung of birds*, either domesticated or wild, affords one of the most powerful of all manures. That of pigeons is the most common in use, merely because it can be procured in the greater quantity. That of domestic poultry is equally efficacious. All are excellent for root crops; and carrots grown with no other manure than pigeons' dung have yielded heavy crops, and free from the attacks of insects. It is an excellent manure for pot plants, but requires to be used sparingly. We use it extensively in pine culture, for camellias, oranges, &c.; and for most rapid-growing plants we use it in a liquid state. Pigeons' dung is hot and stimulating, abounding in the volatile alkaline principle. The fresher it is applied the better, as long keeping, and especially fermentation, of which it is very susceptible, diminishes the

amount of soluble matter. Its principal part is carbonate of ammonia, leaving a considerable residue of carbonate of lime and common salt. The dung of domestic poultry differs only from it in containing a greater portion of silica.

*Rabbit's and deer's dung* is considered even superior to that of pigeons and poultry, and like that should be used while fresh, and in small quantities, when employed as a simple; and when used as a compound, mixed with equal parts of earth to correct its fiery and corrosive fermentation. It forms an excellent top-dressing or mulching for all sorts of rapid-growing pot plants, and may be laid on the surface of the soil in pots to the thickness of half an inch.

*Guano* is the accumulation of the excrements of sea-fowl, found in great quantities in situations where these birds congregate. It has been used by the Peruvians for ages. It was first made known to Europeans in 1804 by specimens sent over by Baron Humboldt. It was afterwards mentioned by Sir H. Davy and Sir Joseph Banks; and about thirty years from its first importation by Humboldt, it began to attract considerable notice in Europe. Various analyses of it have been published; but, in consequence of the extent to which adulteration has been carried, these tests can be of little general advantage. The component soluble parts of genuine guano are, muriate of ammonia, phosphate of ammonia, sulphate of ammonia, sesqui-carbonate of ammonia, oxalate of ammonia, with about equal quantities of water, and soluble organic matter, and urea. The constituent insoluble matters rather exceed the soluble, and of these urate of ammonia and sub-phosphate of lime form by far the largest portion. This manure, before using, should be kept as dry and as little exposed to the air as possible; hence, for horticultural purposes, where no large quantities are required at a time, but the applications are frequent, it is best kept in casks. It is an excellent stimulating manure, beneficial to almost all garden crops, and is found of much service when mixed with composts for pot plants. Water is necessary to bring its fertilising powers into action; a circumstance which appears to be well understood by the Peruvians, who never omit giving water whenever it is applied to the roots of plants. In dry soils, during dry weather, it is not active in its effects; but when applied to growing crops in a liquid state, its effects are speedy and obvious. Indeed, we seldom water any plant or crop, which we wish to stimulate rapidly, without mixing guano with the water. Like bone-dust, it is better adapted to light soils than to strong clays; and its effects are much more obvious in dry and warm climates than in cold and wet ones. In the present adulterated state of guano, it is absurd to lay down rules as to the quantity to be applied to a given space. Such rules have been promulgated with apparently great care; but, we fear, in many cases, not taking into account that not two samples of guano are found to agree in their constituents. Colour is no test, and even weight is not to be depended upon. The following simple test was published by "The Times' Cor-

respondent," and is worth the attention of purchasers: "Burn 200 grains of guano in an open fire, in a common iron ladle; it must be frequently stirred, and after keeping it at a strong red heat for ten minutes, and allowing it to become cold, if the ashes weigh more than 72 grains it is not genuine Peruvian guano."

In applying guano in a dry state, it is advisable to keep it somewhat apart from the seed or roots, because, if of good quality and applied liberally, it is apt to injure them; so it is also, when applied in a liquid form to growing crops, if applied too strong, and allowed to fall on their leaves or tender stems. Like all other potent manures—the dung of birds, rabbits, deer, &c.—it is better to apply a little at a time, and repeat the application. In its liquid state we have found it very beneficial to all the Brassica tribe, to asparagus, rhubarb, and sea-kale.

*Nightsoil* is an excellent manure, computed in value at five times that of horse-dung. It is, however, transient in its effects, and leaves no residuum or earthy matter for decomposition. It is usually mixed with other materials, such as peat, garden soil, vegetable mould, &c., in the proportion of one part of its bulk to five of the others. It is, however, most conveniently managed when in a liquid state; and when reduced by water in the proportion of 1 to 5, is in a fit state to be applied to the soil over the roots of plants, but never over their leaves.

*Liquid manure* is composed of the urine of animals, dissolved excrementitious matter, the draining of dunghills, wash-houses, sculleries, &c. From such sources it is easy to conceive that it is of variable value as a fertiliser, depending upon the proportions which each of these contribute to the manure-tank. Its importance in culture is daily becoming more valued and understood. Its effects are of the most active description, because it is, as it were, the already prepared food of plants. The Chinese and Flemings, who have employed it for ages, and place great reliance upon it, allow it to putrefy in large tanks, and dilute it with water previous to using. Chemists assert that putrefaction is not only useless but actually injurious, causing the soluble matter to dissipate; and also, that in an unmixed state it would contain too much animal matter to form a fluid fit for the roots of plants to take up by absorption. On the other hand, they admit that urine, in a putrid state, abounds in ammoniacal salts, and is less active than when in a fresh state, is nevertheless a very powerful fertiliser. From the way in which it is generally collected—namely, conveyed to a reservoir or tank—it follows that putrefaction can scarcely be prevented, as it has often to remain for days, or even weeks, accumulating before it is required for use. Opinions as to the relative value of solid and liquid manures are as yet greatly at variance; the cost of its application, when applied upon a large scale, is no doubt a strong argument against its use, and this the more so when it has to be conveyed to a considerable distance, and where steam or mechanical power, and great extent of pipes, are required for its transport. According to the calculations made by Mr Stephens on the sewerage water of Lon-

don, it is stated that 560 tons of water only afford one ton of fertilising ingredients; and if this estimate is correct, then would we say sewerage water would be one of the most expensive applications that could be applied to any land. But the sewerage water of London is very different from liquid manure collected in private establishments, because it is so much attenuated in consequence of the extraordinary supply of water brought into London for domestic and other purposes, and the enormous quantity of rain water which falls on the general surface, all of which, excepting what little is lost by evaporation, finds its way into the common sewers, and is mixed with the materials which constitute the whole mass, and thereby greatly reduces its manurial value. From this it is quite evident, that, in the management of a liquid-manure tank, care should be taken that a limited quantity only of rain or other water be admitted into it—perhaps not more than sufficient to flush the drains occasionally out. The arguments brought forward against liquid manure, based on the analysis of the sewerage water of towns, scarcely apply to the liquid manure procured from private dwellings, or even well regulated farmyards; and it is from these sources that liquid manure applied to horticultural purposes is derived.

The urine of animals possesses greater value than solid dung, but is liable to great loss when not properly treated. The ammonia, which is one of its principal ingredients, is found in greatest quantity when putrefaction has taken place; but as ammonia is a highly volatile substance, it evaporates rapidly from the watery solution; and when this evaporation is allowed to take place, then liquid manure ceases to be so valuable as it otherwise would be. With little trouble this evaporation may be prevented. Sulphuric acid and sulphate of iron, both cheap articles, if mixed with the liquid in the collecting tank, will fix the ammonia; for liquid manure containing an average amount of ammonia, 1 lb. of acid to 150 lb. of liquid will be sufficient; and where a greater or a lesser amount of ammonia is contained, a greater or lesser quantity of acid will be required.

The acid should be diluted with water before throwing into the tank. Sulphuric acid in no way affects the value of liquid manure as a fertiliser; it only prevents the loss of ammonia, as the compound it forms with it does not become volatile under the temperature of boiling water. Indeed, experience has proved that its value is much enhanced by the addition of the acid. From the experiments of Mr Kinninmonth, quoted in "Morton's Cyclopaedia," "3000 gallons of cows' urine, to which sulphuric acid has been added, are equal in fertilising value to 6 cwt. of Peruvian guano, and superior to 20 cwt. of farmyard dung. To 160 gallons of urine he adds 3 lb. of acid diluted with water." However little value some chemists and many agriculturists may place on the drainings of the dunghill, or on liquid manure properly collected and prepared, gardeners place great reliance on it, and agree with Nicol, who emphatically declared it to be "the nectar of

vegetation.' The analysis of Professor Johnston has shown that liquid manure contains, in a soluble state, every element necessary to the growth of plants; and also that the drainings of the dunghill are more valuable than urine alone, containing as it does a considerable portion of phosphate of lime, as well as an appreciable amount of silica in a soluble state, neither of which are found in urine alone.

Liquid manure is most beneficially applied to the roots of plants while in a vigorous growing state. It can be applied to them also when solid manures cannot, as in the case of vines and fruit-trees, plants in pots, and to culinary vegetables, at any time during their active existence. To prevent unnecessary saturation, it should be as little attenuated as possible; and, to prevent chilling the roots of tender plants, it should be heated to from 60° to 100°. With these precautions it may be applied to all plants with beneficial effects.

*Ammoniacal liquor* is a solution of ammonia, partly caustic and partly combined with carbonic acid and sulphuretted hydrogen. This is a powerful fertiliser, but is much too strong to be applied to crops in an unmixed state: it requires to be attenuated by the addition of from four to six times its bulk of water. In this state it may be advantageously applied to the roots of growing crops, such as all the Brassicæ, spinach, asparagus, &c. Of this excellent fertiliser Mr Solly remarks, "In consequence of the volatility and caustic nature of free ammonia, it is found advisable for most purposes to fix the ammonia of gas liquor. This may either be done with an acid, or with gypsum or sulphate of iron: a cheap acid like the sulphuric is, generally speaking, the most convenient."

Fish, blubber, and the residue of many manufactured materials composed of animal or vegetable substances, have been used with considerable effect to most soils and to most crops.

Charcoal and the ashes of trees, shrubs, and all vegetables, whether in a living or dead state, afford a considerable amount of fertilising material; but all those, to be useful, must be burned under a slow smouldering fire. When slowly consumed they contain the fixed alkaline salt called potash, which is extracted by lixiviation and crystallisation. Wood ashes contain soluble salts, earthy phosphates, and carbonates, silica, and metallic oxides, differing in quantity and composition in different plants. Vegetable ashes contain lime, potash, soda, silica, magnesia, and the sulphuric, carbonic, phosphoric, and muriatic acids, with oxide of iron and magnesia; but the products differ very much in different plants. These ashes should be kept perfectly dry after being obtained, as water washes out the alkali, leaving only the insoluble and earthy parts behind. Burned clay and charred peat stand in near relation to these.

A long list of organic manures might be given, but the above are those of greatest importance, and, if rightly prepared and applied, may be considered sufficient for all practical uses. It is not in the deficiency in point of numbers, but in the preparation and application of manures, that we are so far behind.

### § 3.—INORGANIC MANURES.

Of all inorganic or mineral manures lime is the most important. It is found existing in the composition of most plants. In one form or other it is found in most soils—in calcareous ones abundantly, in silicious soils sparingly, and in fertile loams in moderate yet sufficient quantities, suitable to the plants produced on them. Lime, considered as a manure applicable to horticultural purposes, ranks under the five following heads:—

*Quick or hot lime* is valued for rendering soluble organic matters, such as vegetable or animal manures already in the soil, and is in that state when it is taken from the kiln, after the water and carbonic acid are driven off during the process of burning. In this state it has a powerful attraction for water, and when applied to the soil, greatly assists in converting the woody fibre and other organic matters into *humus*, forming what is called lumate of lime. The carbonic acid gas which may exist in the soil, or is supplied by water or the atmosphere, reduces the lumate of lime to a soluble state, and converts it into a fit food for plants. Quick or caustic lime is especially useful in soils rich in humus, as most all old garden-soils are. It is also useful in soils containing sulphate of iron, by decomposing that salt which is so hurtful to vegetation. It also renders inert matter, such as dead peat, nutritive and useful to plants.

*Mild lime* is lime which has been exposed to the action of the atmosphere for some time after burning. Its action upon vegetable substances is altogether different from that of quick or hot lime, inasmuch as it prevents the too rapid decomposition of substances already dissolved, acting in this respect similarly to chalk.

Quick lime is most advantageously applied to soils abounding in inert vegetable matter; mild lime, to soils naturally deficient in a proper amount of calcareous matter, which may be determined by their not effervescing when acids are applied to them. "When a soil deficient in calcareous matter contains much soluble vegetable manure, the application of quick lime should always be avoided, as it either tends to decompose the soluble matters by uniting to these carbon and oxygen, so as to become mild lime, or combines with the soluble matters, and forms compounds having less attraction for water than the pure vegetable substance. The case is the same with respect to most animal manures, but the operation of the lime is different in different cases, and depends on the nature of the animal matter to which it is applied. Lime should never be applied along with animal manures, unless they are too rich, or for the purpose of preventing noxious effluvia."—*Encyc. of Gard.*, p. 490. In regard to the season of application, Mr Donaldson remarks, "Autumn is not to be recommended, owing to the solubility of lime in water, and the want of the summer heats, to develop the action of the lime on the substances in the soil. Caloric must be held as one chief spring of chemical affinity; it dilates bodies, separates the particles, diminishes the attraction for each other, and proportionably augments the attraction of

the particles of adjacent bodies, and consequently produces combinations, and facilitates reciprocal unions. The winter will chill the operations, and at that time there is no growing crop to derive any present benefit." And in regard to the condition of the soil, when lime is to be applied, the same authority remarks, "Lime being reduced to a finely pulverised state by calcination, it requires the soil to be, if possible, equally well prepared with itself; for between a variety of finely-blended ingredients there will be produced a number of reciprocal actions and affinities of the different parts, that would not happen in a smaller quantity of these substances in a more aggregated and cohesive state." Besides, as a manure, lime is useful in all garden soils which contain, to a greater or less extent, snails, slugs, and insects, constantly preying on the crops cultivated.

An opinion has long existed against the use of lime containing magnesia. "Such lime," says Mr Edward Solly, "is in general objectionable as a manure. It is probable that the tendency which magnesia has to remain caustic for a long time, absorbing carbonic acid but slowly from the air, is the cause of this." Magnesian limestone, though it has been found to injure crops, has yet been used with good effect in some cases. "When a magnesian limestone is burned, the magnesia is deprived of carbonic acid much sooner than the lime; and if there is not much vegetable or animal matter in the soil, to supply by its decomposition carbonic acid, the magnesia will remain for a long while in the caustic state, in which state it acts as a poison to certain vegetables."—*Encyc. of Gard.*, p. 490. On the other hand, Mr Donaldson, from his own practical experience, says, "On one field a double allowance, or 400 bushels to an acre, was applied as an experiment to test the noxious quality of the lime. In every case the application was attended with the very best success, and for several years the green and culmiferous crops were excellent; and on the ground where the double allowance was applied, the crops showed a great superiority. Here was no damage from magnesian lime, but very great benefit." Different kinds of lime no doubt produce different effects, but that none produce the injurious effect noted above is, we think, more than probable. Limestone rocks containing alumina and silica produce a poorer lime than pure limestone, but it is only their poverty in calcareous matter that renders them less valuable, and certainly no noxious quality to affect vegetation exists in them.

*Chalk* is a calcareous formation, supposed to be composed, according to recent microscopical observations, of animalcules so exceedingly minute that one cubic inch of it contains upwards of a million of them. It is of three kinds—hard chalk, soft chalk, and chalk marl. Hard chalk is burned, and used in the same way as lime; soft chalk is dug from pits, and when spread on the surface of the ground falls into a fine powder, and is then readily incorporated with the soil. Chalk marl is not very abundant, and when found it is used in much the same way as the last. As a manure, chalk acts much in the same way as lime, only it is considered much less powerful

in its effects. It also acts mechanically on soils, rendering strong clays more easily worked, correcting acidity in sour lands, and retaining moisture in such as are very light, burning, or sandy. Like shells and shell sand, it is useful to soils naturally deficient in calcareous matter.

*Sulphate of lime or gypsum* is also a calcareous formation, or limestone in combination with sulphuric acid. It is useful in soils deficient in calcareous matter, and to some extent absorbs the ammonia from the air, and yields it to plants in greater abundance than they could otherwise obtain it.

*Phosphate of lime* forms a constituent in almost all plants, therefore its presence in any matter, or in its native pure state, is useful as a manure. It is present in excrementitious substances, and to a considerable extent in the straw forming farmyard dung, and is a combination of phosphoric acid and lime.

*Nitrate of potash*, which is the chemical name of nitre or saltpetre, when reduced to a powder by bruising, and applied during wet weather as a top-dressing at the rate of one or two cwt. to the acre, appears to act beneficially on loams and clays, and the reverse on light sandy soils.

*Nitrate of soda*, a compound of fossil alkali, is soda combined with nitric acid. It is used in the same manner as the last, and thought by some equal to it in affording nourishment to plants.

It has been remarked by Mr Solly, in "Rural Chemistry," p. 146, that "the nature of the influence which nitrates exert in vegetation is but little understood. Some plants, such as the sunflower, tobacco, lettuce, and many others, always contain more or less of these salts. Others do not contain them, but, when supplied with nitrates, are subsequently found to contain the base without the acid. The soda, potash, or lime is combined with some organic acid, whilst the nitric acid has disappeared. It is probable that, in these cases, the nitrogen of the acid is assimilated by the plant, or that it assists in the formation of gluten and albumen. Nitrates can have but very little value as manures on the soils which naturally contain salts of nitric acid, or which, in consequence of the substances they contain, are constantly forming nitrates. On soils containing neither nitrates nor other alkaline salts, they appear to produce very beneficial effects. These remarks apply equally to nitrate of soda and nitrate of potash; at least similar effects are produced by the two salts as far as regards the increased formation of gluten and albumen."

*Common salt* is a combination of soda with muriatic acid. This, with several other saline substances, has been long employed as a manure, and the results have been as various as the applications themselves. It is employed, no doubt, with marked advantage to plants, natives of the sea-coast, such as asparagus, sea-kale, &c., and in such cases is applied by sowing it on the surface previous to rain, and at the rate of from 16 to 20 bushels per acre, this being repeated two or three times during the year. Salt is found in every animal and vegetable manure. It is detected in many plants, and consequently is of advantage in stimulating vegetable growth, as

well as in the destruction of numerous insects. Notwithstanding, Mr Solly remarks of saline matter, "Nearly all that can at present be said respecting saline manure is, that the addition to the soil, in moderate quantity, of those substances which plants are found to contain, is always good. The mode in which they act, and the office they perform in the nutrition of plants, is as yet but very imperfectly understood."

*Ashes* constitute an important class in manures, differing, however, in their effects, according to the substance which has undergone the process of burning, and the manner in which the process has been accomplished. The ashes of all vegetable substances consist principally of those substances which plants require, as charcoal, lime, phosphoric acid, and alkaline salts. Of these, charcoal or carbon is the most valuable; and hence, to secure it in the greatest quantity, the process of burning should be carried on as slowly as possible; and this is best effected by covering up the mass while burning, and admitting no more air than just sufficient to keep up a smouldering fire. The ashes of all vegetables contain almost the same constituent parts, and are found useful in all soils, and to the majority of crops. They should always be applied while newly burned, as they lose much of their value by keeping, even although kept under cover. A medium quantity of vegetable ashes may be taken at 1 lb. weight to the square yard. Coal-ashes are less valuable as a manure; but as they are to be had in much greater abundance than any other, their use should not be disregarded. The finer parts only should be employed, as the half-consumed coal and the vitrified cinder can be of little use. The finer parts, separated by sifting, contain alumina, carbon, silica, carbonate of lime, oxide of iron, sulphate of lime, and potash. Their chief value appears to consist in the carbon and lime they contain.

*Soot* consists principally of carbon, with a considerable portion of salts of ammonia, which it obtains during the combustion of the coal: these are, however, extremely volatile, and hence much of them is lost. Soot is one of the best of all manures for garden ground; its effects, however, last only during one crop, and its application should coincide with the time of sowing or plant-

ing. It is beneficial also as being destructive to insects: the quantity applied may be from 40 to 50 bushels per acre.

It is not from any want of manures that any land need be left in a state of comparative sterility, their value depends on their proper accumulation, preservation, and application; yet, for all that has been written upon the subject, we see in all directions the very essence of fertility allowed to run to unprofitable waste. The following paragraph from "Donaldson on Soils and Manures," p. 110, is deserving the especial attention of cultivators: "The effects of manures of all sorts depend much on the quality of the land to which they are applied, and also to the state of preparation of the soil, at the time when the substances come in contact with each other. Finely reduced and pulverised bodies cannot mix with those of a grosser form. Masses, clods, and lumps, either of homogeneous or heterogeneous substances, will lie together, and remain in the original state of cohesion or aggregation; but no affinity or composition takes place at sensible distances, and consequently no results follow from the combined influences of the bodies in union. The contact of a pulverised substance with a mass of gross formation cannot produce the effects of combination; the finer particles of the former touch only the external surface of the latter, the interior parts remaining unaffected and unavailable for the purposes and effects of alteration." The profitable application, therefore, of manures, depends on deeply working the soil, reducing it, during the operation of turning, to a pulverised state, blending the manurial application thoroughly with it, and never allowing it to lie long undisturbed, or to become exhausted by heavy cropping and scanty applications of manure. The land must be kept in constant possession of decomposing animal and vegetable substances, by the frequent application of putrescent manures; and if so done, the mineraling reagents we have referred to may then be applied with a certainty of remunerating the cultivator for his expense and labour, but no direct dependence should be placed on mineral manures alone, and far less on the compounds sold as artificial fertilisers.

THE  
HARDY FRUIT GARDEN.

---

INTRODUCTION.

§ 1.—SELECTION OF KINDS, ETC.

IN no department of horticulture has greater progress been made within this last quarter of a century, than in the production of improved varieties of fruits, and the superior management of the trees and plants that produce them. In both cases there was ample room for amendment. For the former, we are mainly indebted to our Continental neighbours, both for the numerous fine varieties we have received from them, and also for the impetus the experiments of Dr Van Mons, and other Flemish pomologists, gave to those of this country, in rearing new varieties from seed. For the latter, not only we, but they also, are indebted to the perseverance, skill, and superior intelligence of such men as Rivers, Thompson, Errington, Fleming, Spencer, Harrison, &c., who, carrying out the theories laid down by Lindley, Knight, Hayward, &c., and even establishing new ones of their own, have reduced the science of fruit-tree management to principles founded on reason and a correct physiological basis. Equally great has been the advance in the no less important part of the science, the establishment of a correct nomenclature, for which we were at first under eminent obligations to the Horticultural Society of London, by the publication of their fruit catalogue, in which the names of a vast number of fruits have been determined, by comparisons drawn from trees grown in their own garden. One of the many names previously given to the same variety in different parts of the kingdom has been selected as the standard, and the others given merely as synonyms. This was a great boon to fruit-growers, and, to a certain extent, raised up a spirit of observation and inquiry amongst them, the advantages of which are so obvious as to require hardly any comment from us. The task was herculean; and, without the means at command of so important a society, could not have been satisfactorily carried out. That such a first effort

should have attained a perfect result, it would be unreasonable to expect. It, however, so far paved the way for others to complete a task so creditably begun. The publication of the "Pomological Magazine," under the auspices of that Society, the "Guide to the Orchard," by Mr G. Lindley, and "The Orchard" by ourselves, subsequently followed; and these three works have done more than all the others that preceded them to render the nomenclature of fruits intelligible to general readers.

The pomological work projected by Mr R. Hogg, if equal to the excellent specimen he has given us in his "British Pomology," which includes the apple only—and we have no doubt it will be so—will, from the published material at his command, collected by others, and his own thorough practical knowledge of the subject, place pomological nomenclature in Britain on a basis superior to that of any other country in the world.

Following up such examples, we have given copious descriptive lists of fruits. Our object, however, has been directed more to a selection of the best kinds suited to the variable climate of Britain, and also to its different localities, than to any attempt at a general description, which, in a work like the present, would be quite out of place. Our descriptions are brief, but, we hope, sufficiently clear for all purposes of practical cultivation; and our recommendations only given where experience, during a long and extensive practice in various parts of the kingdom, justifies them. We have throughout steadily kept in view the exclusion of bad and inferior sorts, and passed unnoticed some few new varieties, with regard to the merits and defects of which we have not as yet had an opportunity of satisfying ourselves. The advantage of giving the synonyms must be apparent to most, as on looking over nursery catalogues, where too often synonyms are disregarded, a person about to form a selection of fruits has to wade through the list of names, and probably, after fixing on

fifty, as he supposes, different sorts, finds, upon consulting a list similar to our own, where the synonyms are given, that he has not more than one-third of the number of really distinct varieties in his selection, and that the remainder are only different names for the few he finds to be really distinct. And well it is for him who has consulted such a list, for, had he not, it is probable his misfortune would not be discovered until the trees had arrived at a bearing state—a loss both of time and of hope. In illustration of this, we may state that a person not well acquainted with such matters, in purchasing twenty peach trees, might find, when they fruited, he had in reality got only one sort, namely, the *Grosse mignonne*, which has no less than twenty-three English synonyms besides several French ones, and all, it must be admitted, very taking and popular names too.

In pears, apples, cherries, &c., similar instances, although not to the same extent, occur; and this confusion exists (as in the case of the peach referred to) more generally with the very best sorts than with those of inferior quality.

In former times, not only our commercial orchards, but many of our best private gardens, were encumbered with fruit trees, few of which had much claim on the attention of the cultivator—a fact which a reference to the nursery catalogues of the early part of the present century, or a glance back at our early days, will sufficiently prove. These things are now greatly altered, so far as the leading nursery catalogues and the best private gardens are concerned; but we regret to see little improvement taking place in the cider orchards of England, and the large commercial orchards in Scotland. The former, in a commercial point of view, require great amendment, and the attention of cider-makers should be directed more to chemistry than to “use and wont;” the latter, if not speedily remodelled, had better be utterly destroyed, as no one will use such inferior fruit as is grown in them, while they can obtain a superior article at the same cost, brought from Holland, France, or Germany. Not that we think the fruits imported from either of these countries, although they possess greater natural advantages in regard to climate than our own, are in general equal to what might be produced at home, were we to discard our inferior sorts, and cultivate such improved sorts as are quite suitable to our climate. If this is not done, there is no doubt that the land at present occupied as orchard ground would be far more profitably employed in the production of agricultural crops. We believe there are few situations, either in England or Scotland, dedicated to the production of fruit, that, under good management and a judicious selection of sorts, might not produce fruit equal, and in many cases superior, to that imported. Both remain nearly stationary, as regards culture and selection; and while they remain in their present state, they must continue to be unprofitable to their owners.

In market-gardening considerable improvement has taken place—a result arising from competition from abroad; and the day is not far distant when the trashy fruits which at present

cumber and greatly deteriorate other crops in such gardens, both in England and Scotland, will be removed, and their places occupied with better sorts. This was done almost simultaneously by most of the large commercial growers about London, as soon as the superior Flemish and other pears were made known to them. Apples and all other fruits underwent a similar change; so that the kinds found in the market thirty years ago, with the exception of a few good and standard sorts, are now almost unknown even by name. A similar improvement has taken place in most private gardens by the introduction of sorts of the very highest character, possessing the properties of ripening early and keeping late, thus spreading the fruit season over the greater part of the year, instead of its covering, as formerly, scarcely half of that period.

We would remind those (and we know there are many such) who, from a mistaken notion of economy, still allow their gardens to be crowded with old and worthless sorts and worn-out trees, producing precarious crops—and those on walls in general towards the extremities of their branches, and of very inferior quality—how much they lose, both in quantity and quality, and how much they would gain by rooting such trees out, and planting those of higher merit. There is no profit in very large fruit-trees: if standards, they scarcely repay the value of the ground they occupy; and if on walls, as we have stated above, scarcely one-sixth of the surface is made available for the production of fruit.

Trees of moderate size afford a greater variety, because a greater number can be planted in a given space, and, if managed as recommended by the best writers of the present day, they will come into bearing a year or two after planting, will be most productive, and continue in health and productiveness, if rightly treated, for a quarter of a century—quite long enough for any fruit-bearing tree, exposed to our variable climate, to be allowed to exist. No doubt there are some exceptions to this rule, but they are very few indeed. In the selection of hardy fruits much discrimination is required, so as to adapt the sorts to the requirements of the owner, as well as to the situation, soil, and climate where they are to grow. Over soil we have complete control; over situation and climate we have comparatively little, and here it is that the judgment of the planter is called into action. Latitude should weigh with him much less than altitude; for experience teaches us that many excellent fruits will arrive at great perfection at 100 feet of altitude, which would scarcely ripen at all at double that height in the same latitude. Some localities are, however, from natural causes, little understood, better adapted to the ripening of fruit than others, even in the same latitude, and at the same elevation. The green gage plum we may instance as an extraordinary example of this: it is found to ripen, as a standard, to greater perfection at Traquair, from 400 to 500 feet above the level of the sea, than it does at Dalkeith, which is only 100 feet—the two places being within half a degree of each other. The gar-

dens at Airthrey, at 150 feet altitude, situated at the base of the Ochil hills, have long been noted for the size and excellenc of their peaches and pears; indeed, those that we have seen of the latter equal any we ever saw grown in the vicinity of London; while in gardens at the same altitude, on the southern banks of the Forth, with equal skill and attention, the same results do not occur. Figs ripen against the wall at Preston Hall, 412 feet above the level of the sea, better than they do at Dalkeith or Melville Castle, only a quarter of that height. The peach, the apricot, and many of our finer apples and pears, ripen in some parts of Ross-shire better than they do in many parts of Northumberland, even at the same height above the sea. The apricot ripens to perfection in many places on the eastern coast of Scotland, at an altitude where it is scarcely possible for them even to exist on the western shores.

Altitude, or elevation above the level of the sea, is considered by most writers on climate, &c., equivalent, as regards the warmth or coldness of a locality, to receding whether north or south from the line—600 feet of altitude being thought equal to a degree. These calculations, however correct they may be as general principles, are in reality of little importance to the British horticulturist. From the insular position of our country, its hilly and diversified surface, as well as its being situated between the parallels of 50° and 58° 40' of north latitude, great and marked inequalities of heat, cold, and moisture occur over its surface, all of which operate powerfully on the productions of his care. The geographical position has more influence on the cultivation of fruits, &c., than the difference in altitude below that point at which fruits cease to ripen. Cultivation has also a great effect on this: drainage, shelter, and exposure, will elevate the temperature, and improve the climate in one situation over that of another at the same altitude, and render the soil capable of raising a higher class of vegetable products, as well as mitigate the effects of certain baneful atmospheric influences. The geological series, also, produces a very considerable influence, both physical and chemical, upon the superincumbent soil, irrespective of their exact altitude. Professor Johnston, struck with this fact in travelling through Wigtonshire, remarks, in "Letters on Scottish Agriculture," that, in passing an "imaginary line, the husbandry changes, the soil seems more barren, the people more indolent, and their methods more primitive. You ask the reason, and you are told that the climate is unfavourable to profitable culture. But if, in the midst of this broad tract of country, a patch of limestone, or trap, or old red sandstone appear, all at once the difficulties appear to vanish, and heaven and earth seem to conspire in rewarding the diligent cultivator of the soil." The same holds good in the cultivation of fruit trees, which are so often found to prosper upon such formations, while they linger out an unprofitable existence 100 or 200 feet lower. The influence of elevation above the level of the sea is little understood, nor has it been sufficiently attended to. Sir Thomas Brisbane and Mr Gal-

braith, in "Edinburgh New Philosophical Journal," have calculated the decrease in temperature to be 1° for every 212 feet of altitude—in latitude, 55°–57°; and Mr Hewitt Watson, in "Magazine of Natural History," vol. i. p. 444, raises it to 239 feet, between 53° and 59°; admitting, at the same time, that neither of these estimates are worthy of implicit reliance. Others state the decrease of temperature at 1° for 300 feet in perpendicular elevation. With such uncertain data regarding altitude, little advantage can be taken in selecting a situation either for a garden or orchard. We have, in vol. i. p. 20, spoken of the advantages of rather elevated situations for gardens in general; and, in addition to the opinions there offered, we may add, that fruit-tree gardens and orchards should never be established in low-lying places, because they are of all others the most subject to the baneful effects of rimes and frosts.

The primary object, therefore, to be kept in view in the selection of fruits for any particular locality, is to ascertain its climate and circumstances, to draw conclusions either from those fruits which prosper in such places, or from those nearest approaching thereto. Perfection is not to be arrived at at first; for, from what has been briefly stated above, there are certain circumstances of which man remains as yet comparatively ignorant, which may lead to satisfactory results, or the reverse.

We have, in various instances, noted those sorts not in general cultivation which are capable of arriving at perfection in northern latitudes, with a view to their being substituted for the inferior sorts supposed alone fit for such localities. In good climates, good fruit, under any ordinary management, may be expected. It is in indifferent or bad climates that we wish to see superior fruits introduced, to the exclusion of the bad ones now grown, and to stimulate growers in carrying out our views.

"We hope to live to see the day," says a sensible writer, in the "Cottage Gardener," No. 221, "when such pears as the Glout moreau, Passe colmar, Ne plus meuris, and Beurre rance, will be offered in Covent Garden market during the winter and spring months, in quantities as great as the Lammas, Williams' Bon chretien, and Bergamots, are during the early autumn. There is no reason why this should not be so, if commercial growers could only be brought to see what their own interest is. The greatest London market-gardeners have long found out the value of such crops, and it is by them that the market and fruiterers are mainly supplied; but the country orchardists are wholly ignorant of, or perfectly easy on the subject." And we as earnestly wish to see the day when our Scotch markets and street vendors' stalls shall be swept of the veriest trash which is hawked about under the name of apples and pears—when the Elshenhalfs, the Pow Megs, and the Grey goodwives, shall give place to the Dunmore, Louis bonne (of Jersey), Urbaniste, &c.

Next to judicious selection is the judicious management of the trees themselves; and amongst the modern improvements in this department is that of keeping a proper balance

between the roots and the branches—by operating more upon the former and less on the latter than has been the practice in bygone days. Not, however, that root-pruning is altogether a new idea, for it was, to a certain extent, recommended by Bradley and others of our older authorities, to be employed upon extraordinary occasions. It has now been reduced to a regular system, and those enlightened individuals who have adopted the practice place much greater reliance upon its due administration than upon all the systems of branch-pruning recommended by former practitioners.

With a view to convey something like a correct idea of fruits, it has been suggested that nurserymen should keep specimens of their fruits, modelled in wax, for the guidance of purchasers. A more economical way would be for the nurserymen of Britain to join together in the publication of a pomological work with coloured figures, somewhat similar to Hooker's "*Pomona Londonensis*," the "*Pomological Magazine*," or the "*Pyrus-Malus Brentfordensis*," the colouring to be under the direction of a competent person, so that uniformity might be insured. We are aware of the cost of such works, and also that neither of the first met with such encouragement as to induce their proprietors to continue them; but in the case to which we refer, a share of the expense ought to be borne by the purchasers as well as by the nurserymen, by a slight additional price on each tree. Both would be equally benefited, and therefore both should bear their share of the expense. The late Messrs Ronalds of Brentford published their beautiful "*Pyrus-Malus Brentfordensis*" at their own cost; and we have their authority for stating that the expense was covered in a few years by the increase in their sales of apple-trees, these being the subjects illustrated. It is not at all unusual for nurserymen to go to the expense of figuring new fruits, but the public have no great confidence in these representations. Some have also had many of their fruits modelled in wax, and very beautifully coloured,—the Messrs Lawson of Edinburgh are doing so at the present time; and, beautifully as these specimens are executed, the misfortune is that the next nurseryman who follows their example, by employing different artists, and procuring the specimens from either better or worse localities, will produce models as different as the fruits themselves would be in these circumstances. It would be otherwise with coloured figures; they would be all engraved from the same plates, and as the colouring is done in general by hand, a great difference might occur here, if not under the direction of some competent individual. No doubt they might be coloured by a process employed in France for several years, and exemplified in the coloured plates in vol. i. of this work; but this process, although much more correct, is attended with much greater expense. Collections of fruits, engraved and coloured, are much more portable, and far less liable to injury than specimens of them modelled in wax, and coloured ever so correctly. A short letterpress description, somewhat in the tabular

form, as adopted by the Horticultural Society in their catalogue of fruits, would not add much to the expense of such a work; and if so executed, sufficient confidence would be placed in it by the public, as it would render both description and figure, as it were, stereotyped, and completely remove the impression formed, that little confidence can be placed in nursery descriptive catalogues in general.

One of our very best pomological writers (Mr Errington) has very lately remarked in "*The Cottage Gardener*,"—"Since the million will have gardens, and possess the desire, without the practical knowledge, to avail themselves of superior fruit, some means should be placed within their reach, of knowing at a glimpse what will suit their purpose. Catalogues they understand not; neither have they time nor inclination to collect facts by a slow and tiresome detail, which would put them in a position with the really practical man, in adapting kinds to their necessities, or as subordinate to their schemes." No doubt, even the best executed coloured figures of fruits would only satisfy so far as actual appearance goes; but this goes a great way with fruit, as well as with a section of humanity it might be deemed rudeness to name. Size, colour, and form would be identified; but flavour, quality, and season of maturity, would only be obtained from a short letterpress description.

Of such importance is the settlement of the nomenclature of fruits, which, notwithstanding all that has been done of late years, is still in a state of very great confusion, that the Belgian government has very recently issued a royal commission, not only with a view of settling the nomenclature, by reducing the names by which they are at present known to a common standard, but also to collect and publish all existing information concerning their merits and cultivation. Much gratified we are that our hints thrown out above have already been thus anticipated, and that to the extent of being carried out under the auspices of one of the most enlightened sovereigns in Europe. We are also glad that the interests of Great Britain in this matter are intrusted to the care of two of her most accomplished pomologists, Mr Rivers and Mr Thompson, who, we have no doubt, will see that the publication is made available to our climate and circumstances—both of which are so different from those of Belgium, that a work adapted to the one country, however creditably executed, would be of little value to the other.

In regard to the extent to which we have carried our select lists of fruits, it may be considered by some that they are too exclusive, while others may think them by far too much extended to come directly under the denomination of selections. Our object has been to bring together as many of the best varieties in each class as we know to be worthy of general cultivation, bearing in mind, at the same time, that many of them that are adapted to one purpose, or to one locality, are by no means fitted for others; and also, that the tastes and requirements of different individuals are nearly as vari-

ous as the kinds of fruits themselves. In forming selections, however, much depends on the space to be planted, the season when the fruit is most required by the owner, whether he is curious in possessing a great variety, or content with a few sorts that may suit his taste and circumstances. As a general rule, we would say, in reference to apples and pears, Plant few of those which ripen early and do not keep long; of other fruits, a just proportion of those that ripen early and ripen late—in both cases with the view of prolonging the season to its utmost limits. Those who are short of room, yet anxious for variety, may accomplish this by working three, four, or more sorts on the same tree. One advantage attending the cultivation of a number of sorts is, that some kinds in some seasons, from a variety of causes, fail altogether, whereas others escape, probably to fail in their turn the succeeding season. From these lists there will be no difficulty in selecting sorts to meet all these emergencies, their adaptation to circumstances, quality, time of ripening, and duration, being all given.

## § 2. THE ORIGIN OF NEW FRUITS.

Concerning the origin of *new varieties* of fruits, little is satisfactorily known. One thing is certain, that under favourable circumstances this process has been going on probably since the creation of fruit trees themselves. That the type of our cultivated apples, for example, is really the crab apple in something like its present state, seems confirmed by the circumstance, that by sowing seeds of any, even of our most highly-improved sorts, a certain disposition is manifested by them to return to their natural or wilding state. Mr Robert Thompson, one of our highest pomological authorities, appears to be of opinion that seedlings of some of our most approved varieties are found only to partake in some degree or other of the properties of their direct parents, but that the greater part of such seedlings more or less affect a wild and inferior character, in no marked manner resembling their parent, in form, colour, nature, time of arriving at maturity, &c. This opinion is borne out by the observations made by some of the best American pomologists, one of whom asserts, that "a hundred seeds of the golden pippin will produce large-leaved apple-trees, bearing fruit of considerable size; but the tastes and colours of each will be different, and none will be the same in kind with the pippin—some will be sweet, some bitter, some sour, some maukish, some aromatic, some yellow, others green, red, or streaked." The same rule also seems to hold good in all countries where the apple is cultivated. Seeing, therefore, that fruits produced from trees not only originated from seeds taken from the same parent tree, but also from seeds taken from the same fruit, possess qualities essentially different, the mystery attending the origin of new varieties of fruits appears the more extraordinary and unaccountable. With these considerations in view, we need not be surprised at the few varieties of superior fruits, which make their appearance, like angels' visits, "few

and far between," nor at the apparent apathy with which experienced growers regard new varieties, however highly recommended, until they have "seen, felt, and tasted," and hence are enabled to judge for themselves. Mr Thompson asserts, and his opinion is borne out by most of our leading vegetable physiologists, "that there is a strong tendency in plants from seeds of cultivated fruit-trees of high character to revert immediately to the state of wildings." The late Mr T. A. Knight, who experimented much in such matters, and with the best results, proved the fact that the wild crab-apple, fertilised by the pollen of a cultivated apple of merit, produces better varieties from seed than can possibly be obtained from seeds taken from the most approved fruits themselves. Seeds of cultivated sorts, or, what are deemed preferable, seeds of wildings originated from cultivated varieties, have been chosen by the Flemish pomologists to sow with a view to obtain improved kinds. These seedling plants they nourish and get into a fruit-bearing state as soon as possible, and from the seeds of these they raise a second generation; thus they go on sowing the seeds of generation after generation, and begin to look out for improved sorts from the second and third generation upwards. This, however, is too early to expect a complete fulfilment of their wishes, although a very perceptible amelioration ensues in each of these generations, and by continuing the process the highest degree of excellence is often at length obtained. For the consolation of experimentalists, we may mention that Dr Van Mons found that good varieties are sometimes obtained from the third generation of apples, in others it may be the fourth or fifth; and in the case of pears, upon which this excellent observer experimented most, the sixth or seventh. An interesting paper on this subject was published some time ago in the "Annales Soc. de Hort. de Paris," by M. Poiteau, headed, "Considerations on the Processes employed by Nurserymen for obtaining better Sorts of Fruits, and on the means by which Nature appears to accomplish the same effect." M. Poiteau commences by observing that improved varieties of our best fruits seldom originate with nurserymen, but owe their origin more to the chance productions found in woods, hedgerows, or in obscure places where the finer sorts are scarcely known. In this opinion he is strengthened by what has occurred in our own country. Our nurserymen and pomologists have acted on the very natural principle that good varieties might be expected from good sorts. In this they have, strange as it may appear, been most signally disappointed; and Duhamel, and other leading French pomologists, failed in the same way. From these failures M. Poiteau concludes that experimentalists are wrong in expecting to obtain at once what can only be produced in time. He seems to infer that seedling apples and pears, for instance, require some years and some cultivation before they can arrive at their fullest state of perfection; thus so far agreeing with the doctrine laid down by Dr Van Mons and others. He may be correct enough in the theory he has formed as to the facility with which the

Americans in the United States so readily procure superior fruits, and at so little trouble: this he attributes to the ignorance or neglect of grafting shown by the earlier settlers, who, in the anxiety to establish a country, neglected to perpetuate their fruit trees by grafting or budding, and had at last recourse to rearing their trees from seeds. From the fruit trees imported into America now about three hundred years ago, seedlings have been originated both by accident and design; and these, having undergone the ameliorating influence of successive generations, have now arrived at that period of their existence which has developed their true and useful character. Climate has, no doubt, much to do in regard to the superiority of American apples; but the breaking up of new lands, as conjectured by M. Poiteau, has little to do with this, or with the production of new or improved fruits; for although such circumstances may improve the quality of the fruit, it cannot alter its physical nature or constitution.

Most of our present esteemed fruits were brought by slow degrees to the West from the East, and principally from Asia and Egypt. Gibbon, in "History of the Decline and Fall of the Roman Empire," vol. i. p. 52, remarks: "In the more remote ages of antiquity, the world was unequally divided. The East was in the immemorial possession of arts and luxury, whilst the West was inhabited by rude and warlike barbarians, who either disdained horticulture, or to whom it was totally unknown. Under the protection of an established government, the productions of happier climates, and the industry of more civilised nations, were gradually introduced into the western countries of Europe; and the natives were encouraged, by an open and profitable commerce, to multiply the former as well as to improve the latter. Almost all the flowers, the herbs, and the fruits that grow in our European gardens are of foreign extraction, which, in many cases, is betrayed even by their names. The apple was a native of Italy; and when the Romans had tasted the richer flavour of the apricot, the peach, the pomegranate, the citron, and the orange, they contented themselves with applying to all their new fruit the common denomination of *apple*, discriminating them from each other by the additional epithet of their country." This progress, in a westerly direction, is going on at the present day; and the fruits of the East are sought for with considerable avidity by the tribes inhabiting the western shores of America. Indeed, as we have elsewhere stated, no very long time has elapsed since neither the grape, the apple, nor the pear existed in that great and progressing continent.

*Improved varieties of fruits accidentally or scientifically produced.*—Accident no doubt gave rise to the first improvements in fruits, and the same operation is still daily going on in nature, almost unheeded by man, until the changes are made manifest to him by their welcome results. The reason why such changes should take place, or why the character first stamped by nature on what has been botanically called species, or highly-marked variety, should have a tendency to disappear in the progeny, has been "a stum-

blingblock to the systematic botanist and to the superficial student in physiological science." But that such a tendency does exist is well known even to very superficial observers; and it has been remarked by those who have looked more closely into the matter, that this tendency is more remarkably developed in some species than in others.

It would be out of place here to attempt to account for this deviation from what has been considered an unalterable law of nature. Taking it, therefore, as an admitted fact that such a disposition does exist, let us consider briefly the share that accident and design have in the matter.

That the scientific process of hybridising is no doubt the most certain mode of procuring improved varieties of fruits is quite clear, yet many varieties, including some of our very best fruits, have been originated by accident. This is exemplified in the case of the Claygate pearmain, scarlet nonpareil, and Hawthornden apples; the two first having been found growing wild in the neighbourhood of Esher, Surrey—the former in a hedgerow, and the other in the garden of a petty public-house; and the remains of the last still exist in the grounds of Sir J. W. Drummond of Hawthornden. Many others have had a similar origin. Of our best pears, Williams' Bon chretien sprung up from seed in the garden of a schoolmaster at Aldermaston in Berkshire; the Elton originated in an orchard in a parish of that name in Herefordshire; while the excellent Chaumontelle was found wild at Chaumontelle in the department of the Oise in France, and the Duchesse d'Angoulême in a similar manner in the forest of Armaille, near Angers. The Elruge, which is one of the best, if not the very best of our nectarines, owes its origin to a nurseryman of the name of Gurlé or Gourlé, at Hoddesdon in Hertfordshire, in the reign of King Charles II., before the doctrine of the sexual intercourse between plants was much known in Britain, from which we may naturally infer that artificial impregnation had not been had recourse to. The Claremont nectarine—a variety of the last—was raised by Mr John Greening, gardener to the Duke of Newcastle, who owned Claremont about the year 1750; and Fairchild's nectarine was raised from seed by a gardener of that name, so long back as previous to 1722—both of these, in all probability, without the aid of artificial fecundation.

In America the same accidental originations have been going on ever since the apple was introduced into that country; and, as accidental varieties of the very highest order there, may be named the Newtown pippin, Baldwin, Swaar, and the Spitzenburghs, as well as many others. Many of their peaches and plums—the Washington, for example—are also of accidental origin. The same thing might be instanced as occurring in all countries, and not only as regards fruits, but also very generally as regards plants.

At what period artificial impregnation, or the crossing one variety with another, began to be practised, with a view to improve either plants or fruits, has not been at all satisfactorily recorded. The process was unknown to the au-

cients, therefore the means of obtaining cross-bred varieties artificially could not have existed prior to the discovery of the sexes in plants, nor in all probability for many years afterwards. Among the first to promulgate the theory of successfully raising fruits from seeds, and the advantage of raising successive generations of the same seedling, was Dr Van Mons of Brussels, who published his views thereon in the "Journal d'Agriculture des Pays Bas," in which he recommends sowing only the seeds of existing varieties of the highest merit, and asserts that, by doing so, varieties will be produced with a much greater chance of improvement than if parents of much less merit were employed. In this view he is supported by the late Mr G. Lindley, who says, in "Guide to the Orchard,"—"In sowing seeds for the purpose of procuring improved varieties, care should be had, not only that the seeds be taken from the finest existing kinds, but also that the most handsome, the largest, and the most perfectly ripened specimens, should be those that supply the seed. A seedling plant will always partake more or less of the character of its parent, the qualities of which are concentrated in the embryo when it has arrived at full maturity. How this concentration takes place, we are as ignorant as why certain constitutional peculiarities are in man transferred from father to son, and from generation to generation; but we know that it does take place. Now, if the general qualities of a given variety are concentrated in the embryo under any circumstances, it is reasonable to suppose that they will be most especially concentrated in a seed taken from that part of a tree in which its peculiar good qualities reside in the highest degree. For instance, in the fruit of an apple growing upon a north wall there is a smaller formation of sugar than in the same variety growing on a south wall; and it can be easily understood that the seed of that fruit which is itself least capable of forming saccharine secretions, will acquire from its parent smaller power of the same nature than if it had been formed within a fruit in which the saccharine principle was abundant. It should, therefore, be always an object with the gardener, in selecting a variety to become the parent of a new sort, to stimulate that variety by every means in his power, to produce the largest and the most fully-ripened fruit it is capable of bearing." The correctness of these opinions is, however, denied by others. Many of our finest varieties of fruits have been no doubt produced by means similar to the above; but by far the greater number are of accidental origin. The writings of Mr Knight, the late Dean of Manchester, Dr Lindley, and a host of others, have thrown much light on this subject in this country; and the physiological authorities on the Continent have contributed abundantly also.

The following excellent fruits may be instanced as a few of the many that have been originated by artificial means: the Napoleon pear was raised by Dr Van Mons at Louvain; the Marie Louise, by the Abbé Duquesne in Belgium; our English Hacon's incomparable, by Mr Hacon of Downham Market, Norfolk; the highly

esteemed Gansel bergamot, by Lieut-General Gansel near Colchester, from a seed of the autumn bergamot; Coe's golden drop plum was produced by a market-gardener of that name at Bury St Edmunds, from a stone of the green gage, the blossom of which had been impregnated by the white magnum bonum, the two trees growing near to each other in his garden; the Downton imperatrice was raised by Mr Knight of Downton Castle, from a seed of the white magnum bonum, fertilised by the pollen of the blue imperatrice; the Pitmaston orange nectarine was raised from a seed of the common Elruge by Mr Williams of Pitmaston; the Acton Scott peach was raised by Mr Knight, and is the offspring of the noblest impregnated with the red nutmeg; the almond peach was raised by the same gentleman from a seed of the sweet almond, the blossom of which had been impregnated by the blossom of a peach. The male parent of the Downton strawberry was the old black, while the female was a kind of scarlet; and in the case of the Elton cherry, the father was the White heart, while the mother was the Graffion, &c.

*The spontaneous change of character in fruit.*—Mr Knight states in the second volume of the "Hort. Trans.," p. 160, that he had a tree of the white magnum bonum plum forty years old, which one year produced on one of its branches red fruit perfectly like the red magnum bonum. He also mentions one of his May Duke cherry-trees, which some years previously had constantly on one of its branches oblong fruit, ripened later, and of greater weight than those on the other parts of the tree. But the most extraordinary instance we know of spontaneous production is that of the excellent and well-known Hunt's tawny nectarine, the origin of which is stated by Mr George Lindley, in "Guide to the Orchard," p. 282, to have been, not through the seminal process, but, as it appears, by a spontaneous effort in nature to enlarge the parts of fructification of the flower of Fairchild's nectarine, by which was produced this admirable variety, so superior to that from which its origin is dated. Mr Lindley remarks, "There appears to me a great singularity in this accidental change of character, and to some it may appear incredible; but I state it as a fact that has happened under my own inspection, being perfectly satisfied that it had never been observed previously by any other person." After enumerating several similar instances, Mr Lindley proceeds, "These, with many other instances of spontaneous production which might be enumerated, lead me to conclude that we may possibly have other varieties, both of plants and fruits, which have not originated from seed."

Peach and nectarine fruit has been frequently produced on the same tree, and even on the same branch. The first instance of this extraordinary freak is recorded in the correspondence between Peter Collinson, an eminent English botanist, and Linnæus; and the last, which we had an opportunity of seeing some years ago, was in the extensive fruit-gardens of the late Mr John Wilmot of Isleworth. The tree was of the Royal George variety, and seldom failed in pro-

ducing fruit of the peach and nectarine on the same branch.—(Vide art. THE PEACH.)

The mountaineer peach comes almost as often smooth as downy, and was raised between the red nutmeg peach and the violette hâtive nectarine, conclusive enough evidence of their common origin.

*Native locality of fruits.*—All fruits appear to thrive best, with the least amount of care, in the locality in which they originated. This is instanced in many cases in our own country, and even more strikingly so in America, where we find that the Newtown pippin and the Esopus Spitzenburgh are the apples of New York; Peck's pleasant, and the Seek-no-farther, are those of Connecticut; the Baldwin, and the Roxbury russet, the leading kinds in Massachusetts, &c.

### § 3. ON THE DURATION, IN A HEALTHY STATE, OF FRUIT TREES.

The late eminent Mr T. A. Knight about half a century ago started an opinion that every variety of fruit tree had assigned to it a limited period of existence, and, as the end of that period approached, unmistakable evidence would be given, by the declining health and vigour of the trees, and also of the quality of the fruit they produced, of its approaching end. Speechly, Williamson, and others, refer to a deterioration which appeared to them to be taking place in the case of the fruit trees of their time; but this they attributed to a change of climate in our country, and anticipated a restoration upon the return of more genial seasons. Our own opinion is strongly in favour of the theory that our seasons, for many years past, have been less genial and less favourable for the growth of fruit than they were formerly; and, however little the mean temperature for the year, or for a series of years, may differ, still we believe our summers are less warm, and our springs much colder, accompanied with a considerable amount of frost, and this at a much later period than heretofore. Before the general employment of the thermometer, which is of comparatively recent date, we had no other means of arriving at anything like correct data as to the temperature of our climate but the historical facts of early harvests, notwithstanding the rude system of agriculture followed, the enormous oaks and other timber trees, the remains of which are abundantly found in bogs, and in altitudes and situations where the oak can scarcely, with all our boasted improvements in arboriculture, now be got to grow at all; for, with the exception of those in Hamilton Park, and a few solitary specimens in other places, we have no oaks in Scotland now bearing any comparison with those of former ages. More pertinent to our present subject, however, are the data furnished by Langley in his "Pomona," who has given us, in the case of almost every fruit cultivated by him at Twickenham near London, the date of the very day when they ripened—dates by no means corresponding with the ripening of the very same sorts, and in the very same locality, at the present time. No doubt tender fruit-trees suffer much

from a succession of cold frosty springs occurring late in the season, and more especially when following a cold wet autumn, when the wood becomes only imperfectly ripened, and also when the latter end of February and March has been sufficiently warm to set the sap in motion, causing the buds to burst forth, and the young shoots and foliage to expand, as they often do thus early, and are as often cut off by frost in April and May. Thus far the healthy duration of fruit trees is seriously affected, and they may no doubt be killed outright.

Returning, however, to Knight's theory—a doctrine, we confess, we were at one time almost a convert to. His views will be best explained by using his own words: "I think I am justified in the conclusion, that all plants of this species" (the apple being that on which his experiments were chiefly made), "propagated from the same stock, partake in some degree of the same life, and will attend the progress of that life, in the habits of its youth, its maturity, and its decay, though they will not be any way affected by any incidental injuries the parent tree may sustain after they are detached from it."—KNIGHT'S *Treatise on the Apple and the Pear*, p. 15.

This opinion received countenance from several eminent pomologists, not only in this country, but on the Continent and America also. Kendrick, in his "New American Orchardist," declares his assent to it. Of the Doyenne pear he says, "This most eminent of all pears has now become (in America) an outcast, intolerable even to sight;" of the excellent brown beurre, "once the best of all pears, now become an outcast." The St Germain "has long since become an abandoned variety," &c. Downing, Hovey, and other American authors, deny that such a fate has befallen these fine fruits; and the healthy existence of them in France, where they have existed from their very origin, as well as their present state in Britain, where they have all been cultivated for a much longer period than they have been in America, proves to us the unsoundness of the doctrine, and the danger of confounding causes and effects. On this Downing very sensibly remarks, in "Fruits and Fruit-trees of America," p. 552: "While we admit that, in the common mode of propagation, varieties are constantly liable to decay or become comparatively worthless, we believe this is owing, not to natural limits set upon the duration of a variety—that it does not depend on the longevity of the parent tree, but upon the care with which the sort is propagated, and the nature of the climate and the soil where the tree is grown. It is," he continues, "a well-established fact, that a seedling tree, if allowed to grow on its own root, is always much longer lived, and often more vigorous, than the same variety when grafted upon another stock; and experience has also proved that, in proportion to the likeness or close relation between the stock and the graft, is the long life of the grafted tree. Thus, a variety of pear, grafted on a healthy pear seedling, lasts almost as long as upon its own roots. Upon a thorn stock it does not endure so long; upon a mountain ash rather less; upon a quince stock still less, until the average life of the pear

tree, when grafted on the quince, is reduced from fifty years—its ordinary duration on the pear stock—to about a dozen years. This," Mr Downing says, "is well known to every practical gardener, and it arises from want of affinity between the quince stock and the pear graft. The latter is rendered dwarf in its habits, bears early, and perishes equally soon." We do not quite agree with Mr Downing as to this very great limitation; but, admitting it even to be so to a certain extent, we would, for many purposes and reasons, retain the quince stock; for longevity, under certain conditions, is of secondary consideration, more especially as pears upon quince stocks produce their fruit so soon after grafting, that there would not be much greater trouble in keeping up a succession of young trees than in doing the same with gooseberries and currants. Following Mr Downing, who says, "Next to this, the apparent decay of a variety is often caused by grafting on unhealthy stocks; for although grafts of very vigorous habit have frequently the power of renovating in some measure, or for a time, the health of the stock, yet the tree, when it arrives at a bearing state, will, sooner or later, suffer from the diseased or feeble nature of the stock.

"Carelessness in selecting scions for grafting is another fertile source of degeneracy in varieties. Every good cultivator is aware that if grafts are cut from the ends of old bearing branches, exhausted by over-bearing, the same feebleness of habit will, in a great degree, be shared by the young graft; and, on the contrary, if the thrifty straight shoots that are thrown out by the upright extremities, or the strong limb sprouts, are selected for grafting, they insure vigorous growth and healthy habit in the graft. Finally, unfavourable soil and climate are powerful agents in deteriorating varieties of fruit trees. Certain sorts that have originated in a cold climate are often shortlived and unproductive when taken to warmer ones, and the reverse. This arises from a want of constitutional fitness for a climate different from its natural one. For this reason the Spitzenburgh apple soon degenerates if planted in the colder parts of New England; and almost all northern sorts, if transplanted to Georgia." And upon the same principle, many fine apples of America will not thrive in England, much less in Scotland. "But this only proves that it is impossible to pass certain natural limits of fitness for climate, and not that the existence of the variety itself is in any way affected by these local failures."

Knights's doctrine was denied by Decandolle, Mr George Lindley, and by many of the most eminent vegetable physiologists. The former of these says, "Varieties will last as long, and remain unchanged as long, as man chooses to take care of them;" and of this we have sufficient evidence in the case of the pearmain, which is the oldest apple on record, and still showing no symptoms of decay; and the same may be said of the Cat's-head, London pippin, Winter queening—or quoining, as written by some, and probably more correctly. The latter observes, in "Guide to the Orchard," p. 16, in reference to the supposed degeneracy of the golden pip-

pin, "I cannot for a moment agree to such an opinion, because we have facts annually before our eyes completely at variance with such an assertion." Mr Knight even set a limit to the existence of a variety, and observes, "that no variety of apple will continue to exist more than two hundred years." Nearly two hundred varieties could be named that have continued thus long, and without those discouraging symptoms he anticipated. Downing remarks, and with great good reason, "that the hardihood of any variety depends greatly upon the circumstances of its origin. When a new variety springs up accidentally from a healthy seed in a semi-natural manner, like the Seckel, the Dix, and other American native sorts, it will usually prove the hardiest. It is as if it were an effort of nature to produce a new individual out of the materials in a progressive state, which garden culture has afforded. Cross-bred seedlings—one parent being of a hardy nature, and both healthy—such as Knight's own seedlings, the monarch and Dunmore pears—are next in hardiness. Lastly, we rank varieties reared by Van Mons' method—that of continually repeating reproductions. This, as Van Mons distinctly states, is an *enfeebling* process, without any compensatory element of vigour. Hence it follows, as a matter of course, that seedlings of the fifth and sixth generations, as are some of his varieties, must in their origin be of feeble habit. Vau Mons himself was fully aware of this, and, therefore, resorted to grafting by copulation"—in fact, root-grafting, as Downing remarks—"well knowing that on common stocks these new varieties would in light soils soon become enfeebled and decayed." Mr Downing seems very averse to grafting on quince stocks, and we believe we can clearly see through this, which, at first sight, may seem prejudice on his part. The climate of America is favourable (that is, around New York, the sphere of Mr D.'s operations) to the production of fruits, at a much earlier age of the trees than with us in Britain; and therefore those means recommended by Mr Rivers, and others of our best fruit-cultivators, are uncalled for. With such a climate we would probably also use the pear stocks; but in a climate such as ours in Britain, and in garden-ground highly manured, we would decidedly, for certain purposes, give the preference to quince stocks. Downing has clearly taken Knight upon the weak side of his theory when he says, "In Knight's original essay on the decay of varieties, he clearly states that the local decline of a variety is mainly owing to neglect, and to grafting on a bad stock. We allude to the fact, repeatedly verified, that healthy young shoots taken from the *roots* of an old variety in apparent decline, produce trees which are vigorous and healthy. The decay," Knight says, "of the power of life in the roots of seedling trees is exceedingly slow comparatively with that in the branches. Scions obtained from the roots of pear-trees two hundred years old, afford grafts which grow with great vigour, and which are often covered with thorns like young seedling stocks; whilst other grafts, taken at the same time from the extremities of the branches of

such trees, present a totally different character, and a very slow and unhealthy growth. Although Mr Downing's remarks are more of a practical nature than of a physiological one, they bear the stamp of keen observation. Physiologists may, nevertheless, differ from him in certain deductions he has drawn.

Knight's theory does not, however, appear to be new, for we find Mortimer, author of some tracts on religious education, and also on husbandry, in or about 1707, setting forth in great grief the constitutional decay of the Kentish pippin—a variety at the present day as healthy as it was at any period of its existence. No doubt, many of the apples and pears of the fifteenth and sixteenth centuries have disappeared, as will not a few originated from seed even in the present century before it has closed. But this very naturally arises from the circumstance of their being superseded by better sorts, or being found inferior to many old ones still in cultivation. Many of the trees in the Herefordshire orchards, to which Mr Knight alludes as being the diseased progeny of others long since dead, having outlived their prescribed period of existence, which he limits to two hundred years,

may ere this, as has been justly remarked by Mr Hogg ("British Pomology," p. 97), have disappeared also, "having performed their part, and fulfilled the end of their existence." The golden pippin, amongst others which Mr Knight names as being now worn out, appears to be in as thriving a condition, when not maltreated, as it was two hundred years ago. In the Brompton Park nursery, Mr Hogg assures us, (p. 97,) the same golden pippin has been cultivated for nearly two centuries, and continued from year to year by grafts taken from the young trees in the nursery quarters. "I never," he says, "saw the least disposition to disease, canker, or decay of any kind; but, on the contrary, a free, vigorous, and healthy growth." The vine, the peach, and the apricot have been propagated by extension since the earliest ages, yet we never hear of a wearing out of any of the varieties of these trees; and this possibly arises from their being treated in a more natural manner, or more care being bestowed on their cultivation, than has been the case with the apple, which, we know from ocular demonstration, is nowhere worse managed than in the very Herefordshire orchards to which Mr Knight refers.

# CHAPTER I.

## PROPAGATION.

NOTWITHSTANDING the close analogy that for the most part exists between the natural economy of animals and vegetables, there are some important points in which they widely differ, and in none more so than in the means of their propagation. All vegetables were created for the sustenance of animals; and hence, wherever the latter exist, the former are to be found. The whole surface of the globe, whether covered with water or not, is replete with vegetation, and that vegetation exists not without its use.

To supply the whole animal creation, it follows that vegetables must be not only exceedingly numerous, but also readily produced—at least, their means of production must be much greater than that of animals themselves. Plants not only produce immense quantities of seeds, but they extend themselves by shoots which run on or under the ground; they are capable of multiplying themselves by roots, tubers, and bulbs, both formed under ground, and in some cases on the leaves and stems; and they produce innumerable buds, each of which, by human art, can be rendered equivalent to a seed, and hence the great facility by which plants are multiplied both by nature and art.

It is probable that something like one hundred thousand species of plants exist; the herbaria of some botanists contain nearly that number in dried specimens. Thirty thousand seven hundred species are enumerated as indigenous or cultivated in Britain alone; and if we include the botanical varieties, and those of cultivated vegetables, fruits, roses, and florists' flowers, eleven or twelve thousand may be added.

### § 1. PROPAGATION BY SEED.

Propagation by seed is the primary and most general process by which plants are multiplied and perpetuated. All plants are so produced, although in many, such as ferns, mosses, algæ, and fungi, the seeds are so small as to be invisible to the naked eye; yet these latter are amongst the most widely diffused of all vegetables. The seeds of the latter are dispersed by a variety of means, by atmospheric and other causes, their minuteness and buoyancy adapting them well for aerial distribution. There is scarcely a point on the globe's surface, or even in the ocean's depths,

where they are not found to exist: the whole atmosphere seems to be replete with them; and when they are brought into contact with solid bodies forming a proper nidus for them, there they take root and flourish. Nor are the plants originated from such apparently slender means proportionably minute; many of them attain an almost gigantic size, as exemplified in many of the Algæ, whose ramified branches extend to the length of hundreds of feet, while the tree ferns rank amongst the monarchs in the tropical forests.

The powers of reproduction by seed are truly immense: a single capsule of the tobacco plant contains about one thousand seeds; one of the common medicinal poppy, eight thousand; while the vanilla plant has been computed to contain from ten to fifteen thousand. Each of these, upon a very moderate calculation, produces from twenty to thirty capsules on each plant. To give some idea of the powers of reproduction amongst cryptogamous plants, we may state that a single frond or leaf of the common spleenwort is estimated to produce one million of seeds.

Most plants originated from seeds resemble their parents in a very striking degree, although, occasionally, deviations of greater or lesser importance occur; hence many of our most valuable plants, and especially fruits and culinary vegetables, have so originated, and when sufficiently marked by symptoms of improvement, are denominated varieties.

All vegetable life commences from seed. Its first stage and after progress are thus described by Dr Lindley in "Introduction to Botany." "If we place a seed in earth at the temperature of 32° Fahr., it will remain inactive till it finally decays; but if it is placed in moist earth above the temperature of 32°, and screened from the action of light, its integument gradually imbibes moisture and swells, oxygen is absorbed, carbonic acid expelled, and the vital action of the embryo commences. It elongates downwards by the radicle, and upwards by the cotyledons, the former penetrating the soil, the latter elevating themselves above it, acquiring a green colour by the deposition of carbon absorbed from the atmosphere in the light, and unfolding in the form of two opposite roundish leaves. This is the first stage of vegetation. The young plant consists of little more than cellular tissue, only an

imperfect development of vascular and fibrous tissue being discoverable in the form of a sort of cylinder of bundles lying just in the centre. The part within the cylinder, at its upper end, is now the medulla, without it the bark; while the cylinder itself is the preparation for the medullary sheath, and consists of vertical fibres passing through cellular tissue, and separates them horizontally in every direction.

"The young root is now absorbing from the earth its nutriment, which passes up to the summit of the plant by the cellular substance of the medulla, and is thence impelled into the cotyledons, where it is aerated and evaporated: such of it as is not fixed to the cotyledons passes down through the bark into the root. The plumula, forced onwards by the current of sap, which is continually impelled upwards from the root, next ascends in the form of a little twig, at the same time sending roots in the form of fibres downwards in the centre of the radicle, which become the earliest portion of wood that is deposited: these fibres by their action now compel the root to emit little ramifications. Previously to the elongation of the plumula, its apex has acquired the rudimentary state of a leaf; this continues to develop as the plumula elongates, until, when the first internodium of the latter ceases to lengthen, the leaf has actually arrived at its complete formation. When fully grown, it repeats in a much more perfect manner the functions previously performed by the cotyledons; it aerates the sap that it receives, and returns the superfluous portion of it downwards through the bark to the root; it also sends fibres down between the medullary sheath and the bark, thus forming the first stratum of wood in the new stem. During these operations, while the plumula is ascending, its leaf forming and acting, and the woody matter created by it descending, the cellular tissue of the stem is forming and expanding horizontally to make room for the new matter forced into it; so that development is going on simultaneously, both in a horizontal and perpendicular direction. This process may not inaptly be compared to that of weaving, the warp being the perpendicular, and the weft the horizontal formation. In order to enable the leaf to perform its functions of aeration completely, it is traversed by veins originating in the medulla, and has delicate evaporatory pores (stomata), which communicate with a highly complex pneumatic system, that extends to almost every part of the plant.

"The plumula having produced its first leaf, others are successfully produced around the axis at its elongating point, all constructed alike, connected with the stem or axis in the same manner, and performing precisely the same functions as have been just described. At last the axis ceases to elongate; the old leaves gradually fall off; the new leaves, instead of expanding after their formation, retain their rudimentary condition, harden, and fold over one another, so as to be a protection to the delicate point of elongation, or, in other words, become the scales of a bud. We have now a shoot with a woody axis, and a distinct pith and bark, and of a more or less conical figure. At the axilla of every

leaf, a bud had been generated during the growth of the axis, so that the shoot, when deprived of its leaves, is covered from end to end with little symmetrically-arranged projecting points, which are the buds. The cause of the perfect shoot being conical is, that, as the wood originates from the base of the leaves, the lower end of the shoot, which has the greatest number of strata, because it has the greatest number of leaves above it, will be the thickest; and the upper end, which has the fewest leaves to distend it by their deposit, will have the least diameter. Thus that part of the stem which has two leaves above it will have wood formed by two successive deposits; that which has nine leaves above it will have wood formed by nine successive deposits, and so on; while the extreme vital point, as it can have no deposit of matter from above, will have no wood, the extremity being merely covered by the rudiments of leaves hereafter to be developed. If at this time a cross section be examined, it will be found that the interior is no longer imperfectly divided into two portions—namely, medulla and skin—as it was when first examined in the same way, but that it has distinctly two internal, perfect, concentric lines, the outer indicating a separation of the bark from the wood, and the inner, a separation of the wood from the medulla: the latter, too, which in the first observation was fleshy, and saturated with humidity, is become distinctly cellular, and altogether or nearly dry." Such is the first progress of a plant from seed.

Air, moisture, darkness, and heat are all indispensable in promoting germination; the absence of them is the cause why seeds found at greater depths in the soil than air penetrates to, vegetate when brought within its influence, and why they remained inactive during the period of their being so deeply immured. What degree of credence may be given to the assertions of those who say they have caused to vegetate the seeds of wheat taken from the tomb of an exhumed mummy, or of raspberry tarts being made of fruit the produce of plants raised from seed taken from a Roman barrow, we shall not stop to investigate further, than by observing that, if these facts are true, an absence of air, or rather oxygen, was the cause of this long-suspended vitality. That seeds do remain for a number of years in a sound state when placed so deep in the ground as to be beyond the influence of oxygen, and probably an insufficiency of moisture, is highly probable; but there is a vast difference between a score or two of years and a few thousands.

When seeds are sown too deep, the effect is that they germinate much slower than if placed nearer the surface, and often, particularly in damp soils and wet seasons, they perish altogether. The following table was drawn up by Petri: Of seed sown at the depth of  $\frac{1}{2}$  an inch,  $\frac{2}{3}$ ths came above ground in 11 days; at 1 inch in depth, all came up in 12 days; at 2 inches,  $\frac{2}{3}$ ths came up in 18 days; at 3 inches,  $\frac{2}{3}$ ths came up in 20 days; at 4 inches,  $\frac{2}{3}$ ths came up in 21 days; at 5 inches,  $\frac{2}{3}$ ths came up in 22 days; at 6 inches,  $\frac{1}{3}$ th came up in 23 days,—showing, therefore, that shallow sowing is the best.

The larger seeds are, such as the acorn and walnut, the deeper they should be placed; while very small seeds, such as rhododendron, &c., should be sown upon a smooth surface, and scarcely covered at all. It is necessary, however, that light be excluded until germination has taken place. Moisture is necessary to germination, and without it seeds would ever remain inactive. The quantity of moisture requisite to cause germination in some seeds is much greater than in others; and hence pease, beans, &c., when hasty vegetation is desired, are often soaked in water for some hours before sowing; and in dry states of the soil, the drills are watered before the seed is committed to them. Decandolle found that a French bean, weighing 544 milligrammes, absorbed 756 of water. The grand secret of keeping seeds in a good state in our seed warehouses is their being kept dry; and if they could be at the same time excluded from air, no doubt their period of vitality would be considerably lengthened. Absence of light is another condition, as has been shown by M. Boitard and others, almost indispensable to germination. In the case of very small seeds which do not admit of being covered with soil, germination will be much assisted if they be covered with bell glasses, either painted black or having a thick piece of cloth laid over them. According to the recent experiments by Mr Hunt, the luminous or light-giving rays, and those nearest the yellow, have a marked effect in impeding germination; while the red or heat-giving rays are favourable to the process, if abundance of water be present; while the blue rays, or those concerned in chemical action or actinism, accelerate the process and cause rapid growth.

The temperature necessary for the germination of seeds extends over a considerable range in the scale of the thermometer. We have stated that 32° Fahr. is the lowest with which we are acquainted at which seeds will germinate, because below that degree water freezes, and cannot, therefore, be absorbed by the tissue of the seed. It is possible, however, that some of the less perfect plants, such as some of the Algæ and Fuci in the arctic regions, may vegetate even below that point. The general range, however, is from 45° to 80° or 90°. Some seeds, such as the rose-acacia, Robinia, pseudo-acacia, and some of the Australian acacias, have been immersed for some minutes in boiling water without their vitality being destroyed. In cultivation, some require the heat of the tropics, while others vegetate freely in the heat of our springs. The highest limit of prolonged temperature which cereal grains can bear in water is stated by Edwards and Colin to be 95°, and the highest they can bear in sand or earth, 113° Fahr. Dr Lindley records a case of the seeds of the raspberry having germinated after being subjected to the boiling point of syrup, which is 230°. The seeds of the annual poa, *Poa annua*, chickweed, *Alsine media*, and various others, will germinate at very little above 32°. These points may therefore be taken as the maximum and minimum of vegetation.

*One seed producing twin plants.*—In the ordinary course of nature one seed produces one

plant as a general rule; but to this there are exceptions, one of which is stated by Mr Thwaites, in "Annals of Natural History," as occurring in the case of a single seed of a hybrid fuchsia producing two plants "extremely different in appearance and character, one of them partaking of the character of *F. fulgens*, and the other of *F. coccinea*," these being the two parents. "It cannot be doubted," he says, "that these very dissimilar structures were the produce of one seed, since they were closely coherent, below the two pairs of cotyledon leaves, into a single cylindrical stem, so that they had subsequently the appearance of being branches of one trunk." It is not improbable that the same thing frequently occurs in the case of forest trees of natural growth, where two apparently distinct trees rise from one root—a circumstance accounted for, but we believe erroneously, by supposing two seeds to have sprung up together, and that, from the closeness of their stems, a species of natural engrafting had taken place while they were very young.

*Vitality of seeds.*—We have stated above, that some seeds are supposed to retain their vitality for two thousand years or more. There are others, if placed under the ordinary conditions natural to them, that lose that power almost immediately after they have arrived at full maturity; many continue sound one year, others two, and some few not only for a greater number of years, but also being improved by keeping. We are not aware that this latter fact has ever been physiologically accounted for, but practically it is known to be the case. The following common instances may be given. Melon and cucumber seeds are improved by age, in so far that they are found to be more productive of fruit, and less prone to grow to branches than when new; cauliflower and most of the brassica tribe are less liable to button or run prematurely into flower; while turnips bulb better, produce less top, and are less liable to run to seed in spring, when the seed is several years old, than if the produce of the preceding season. If such seeds, therefore, be well kept, we would say that they were better when four years old than when one year; and, if this theory be correct—and we think the experience of years goes far to prove it so—that they are in a very fitting state for sowing while under ten years. Gardeners have long seen the importance of this, and hence it is no unusual thing for many to carry about seeds of the two first mentioned in their pocket, that the necessary maturation may be accelerated by the warmth of their bodies. We state this latter case, not as an example to be followed, but as an evidence of the principle. The object aimed at in the cultivation of the plants we have named is not bulk of gross vegetable matter, but to insure an end; and that end is to produce those fruits and vegetables in the highest state of perfection they are capable of arriving at, and most fitted for the purpose for which they are cultivated.

A still more extraordinary instance than those of the mummy wheat, &c., of the protracted vitality of seeds, is to be found in a paper by Mr Kemp, published in the "Annals of Nat.

Hist.," vol. xiii. p. 89. It relates to the discovery of the seeds of plants which upon vegetating were found to be those of *Polygonum*, *Convolvulus*, *Rumen acetosella*, and a species of *Atriplex*. They were found at the bottom of a sand-pit 25 feet deep, about a quarter of a mile west of Melrose. These seeds were imbedded amongst decayed vegetable fibres, resting on a stratum, 8 inches in thickness, of fine sandy clay. Under this stratum was a mass of gravel resting on a mound of the boulder formation 90 feet in thickness, and which Mr Kemp supposes was formed by the action of glaciers. The stratification of fine sand over the seeds was alternated with thin seams of impalpable clay, in both of which traces of carbonaceous decayed wood and minute pebbles were found, resembling much the foundation of a river, as seen when a section is cut through its bed to some depth. These and other circumstances led Mr Kemp to the conclusion that the river Tweed had anciently run in this direction, or that a lake of considerable size had at some very remote period existed here, but which is at present at a considerable distance, and between 50 and 60 feet below the level of the sand quarry. "It is certain," Mr Kemp concludes, "that in the time of the Romans, about two thousand years ago, no lake existed here; and when we reflect on the time necessary to have worn down the barrier of trap rock, and to have drained so large a lake, which must have stood at its highest level whilst the thin layers of sand were deposited over the bed with the vegetable remains, the antiquity of these seeds is truly astonishing, and it is most wonderful that they should have retained their power of germination."

Oily seeds lose their vitality speedily, probably from their power of absorbing oxygen, and the chemical changes thus induced. Some seeds retain their vitality much longer than others: thus the seeds of melons have been kept for forty-one years, maize thirty years, rye forty years, *Mimosa sensitiva* sixty years; and, stranger than all, those of the kidney bean, after being kept for a century, have germinated, while gardeners in general believe that they are of one year's duration only.

Seeds will germinate more speedily, if sown fresh, when nearly ripe, than if they were fully ripe; and in the latter case, if sown immediately, than if kept for some time—say for some months, or a year or two.

Intimately connected with the nature of seeds is the condition of the soil into which they are sown; and hence gardeners bestow both much more labour and care in its preparation than farmers do. All soils must be thoroughly pulverised to render them fit for the reception of the seed, and hence the great necessity of trenching, digging, forking, raking, &c., to reduce the soil to a fit state of fineness. These operations must not, however, be carried on when the soil is wet, else all the labour will be worse than in vain. All soils must be comparatively dry before the seeds are committed to it. The soil, to be in a fit state, upon examination should be found to be composed of small particles sepa-

rated from each other by interstitial spaces or cavities. If wet, these cavities will be full of water instead of air; but if in a proper state, the particles will be sufficiently moist, while the cavities will be dry and charged with air. Nor is it the presence of air alone, although one of the essential conditions of certain germination, that is here required; these cavities admit the solar heat, without which, in early spring, germination would be slowly enforced—so slow, indeed, that many seeds might perish before vegetation could take place.

In light sandy soils, abounding in carbonaceous matter, seeds germinate rapidly; in stiff clayey soils, more tardily; and if imbedded in peat-moss fully charged with water, they would either perish, or remain probably for ages in a dormant state. Most seeds vegetate freely in decayed vegetable mould, with a slight addition of fine sand; others, such as some of the Coniferae, would speedily rot in such a preparation, and succeed best when placed in a more primitive soil.

The following table was drawn up by Adamson, founded on experiments made by him in France, as to the period seeds remain in the ground, after sowing, before germination takes place: "Strawberry blite, beans, mustard, kidney beans, turnips, radishes, 3 days; lettuce and aniseed, 4 days; melon, cucumber, gourd, and cress, 5 days; horse-radish and leek, 6 days; orache, 8 days; purslane, 9 days; cabbage, 10 days; hyssop, 30 days; parsley, 40 to 50 days; almond, chestnut, peach, and peony, 1 year; rose, hawthorn, hazel-nut, and cornel, 2 years."—(*Fam. des Plantes*, vol. i. p. 84.)

The following table was drawn up from experiments made in the botanic garden at Geneva; the seeds were watered similarly, and the temperature to which they were exposed was 53° Fahr. as a medium: Amaranthaceæ, 9 days; Cruciferae, 10 days; Boraginæ, Malvaceæ, Caryophyllæ, 11 days; Compositæ, Convolvulaceæ, Plantaginæ, 12 days; Polygoneæ, 13 days; Campanulaceæ, Leguminosæ, Valerianaceæ, 14 days; Gramineæ, Labiateæ, Solanæ, 15 days; Rosaceæ, 17 days; Ranunculaceæ, 20 days; Onagrariceæ, 22 days; Umbelliferae, 23 days.

The order in which seeds germinate appears often to be very capricious. Many, when sown in spring, vegetate in course of a few days, which, if sown in autumn, would not come up the same year. The seeds of biennials, for the most part, are committed to the ground as soon as they are ripe, vegetate, and become strong plants before winter, and flower the ensuing summer. Heat, moisture, and absence from light, are the conditions necessary to insure germination. The former is a main agent in accelerating this process, and hence seeds are sown, in general, in spring, instead of during winter, although the latter practice is often resorted to in the case of garden pease and beans, with a view to insure their early ripening. This is, however, a questionable practice. Seeds of tender plants are sown in hot-beds, in pots plunged in a mild bottom-heat; and sometimes imperfectly ripened ones are sown, and this has been found to promote their early vegeta-

tion. Steeping seeds for a few hours in warm water has the desired effect, more especially when the soil into which they are to be sown is dry, as often occurs during the heat of summer. Hard seeds, such as walnuts, almonds, &c., are often buried for a day or more in matter in a moderate state of fermentation; and at other times the shell is paired, cut, or filed thin, so as to assist the embryo plant's escape from its hard encasement. The more scientific operations are, watering with chlorine, as first suggested by Baron Humboldt; the application of iodine and bromine, in conjunction with hydrogeu, as proposed by Goppert: both these, as well as oxalic and other acids, have no doubt the effect, when frequently applied, of hastening the process of assimilation, and accelerating vegetation. These have, however, the effect of causing the plants thus hastily brought, into a state of existence to assume a sickly appearance through over-excitement, and not unfrequently many of them die. Dr Hamilton and M. Otto of Berlin made seeds to vegetate, notwithstanding they were from twenty to forty years old. On the use of these, as well as of a diluted solution of chlorine, Dr Lindley, in "Theory of Hort.," remarks, "Theoretically, it would seem that these effects ought to be produced, but general experience does not confirm them; and it may be conceived that the rapid abstraction of carbon, by the presence of an unnaturally large quantity of oxygen, may produce effects as injurious to the health of the seed as the too slow destruction of carbon, in consequence of the languor of the vital principle."

The natural season for sowing seeds is unquestionably as soon as they are ripe, but for the purposes of cultivation it is often necessary to defer this process for a few weeks or months. This is pointed out to us by nature; and, indeed, some seeds are not capable of retaining their vitality many days after they are removed from the plant. Seeds which naturally fall from the plant, either by their weight or by some other means not easily accounted for, secrete themselves in the ground, or amongst moss or leaves, &c., so as to be ready in spring to start into new life. Many vegetate during autumn, and survive the winter, as it were, in an infant state, and are prepared, upon the approach of the warmth of spring, to perform the offices they are destined for. This is remarkably exemplified in the case of most of the plants from North America and California; and these, according to the most approved mode of culture, should be sown as soon as they are ripe; while, again, Mexican and Chilian seeds succeed best when sown in spring. According to Mr Gordon of the Chiswick gardens, the seeds of the trees and shrubs of Europe and of India "should be sown in autumn, and annuals or perennials in the spring. All seeds, of whatever kind, should be sown in dry soil, and not wetted till they begin to vegetate. In the case of old or sickly seeds, to water them at the time of sowing is to insure their destruction by rotting. Shading is to be preferred to watering; and one of the best constructions for the purpose is a pit glazed with double sashes. Finally, all seed-

lings should be potted or transplanted as soon as possible, except hulbs."

Experiments in seed-sowing are and have been numerous: that of sowing them in snow, as exemplified by M. Lucas, and detailed in the "Garten Zeitung," is one of the most extraordinary, and least in accordance with the laws of vegetable physiology, as snow must be nearly at the temperature of 32°; hence they are placed at the very lowest point of temperature at which germination can take place. For what reason M. Lucas follows this unusual course does not very clearly appear. The majority of seeds experimented upon by him were those of alpine plants, which of necessity in nature vegetate at the lowest temperatures. The idea of sowing seeds in new-fallen snow, or in that which has been frozen in ice-houses, and immediately placing them in a hot-house with a temperature of 60° or 65° Fahr., can amount to nothing other than sowing the seeds in the usual way, and drenching them with the coldest water; and that, with a view to accelerate their vegetation, is contrary, in the fullest extreme, to what has been considered the highest principle of good culture. In the Munich botanic garden, experiments were first tried, and frequently since in Britain, of sowing seeds in powdered charcoal, the results being an advance of one day in the process of germination. Minute seeds are often sown on the surface of charcoal blocks, on pieces of sandstone, and woollen cloth kept moist, but with effects of small importance to the general cultivator, although valuable to the botanical gardener, as, by this means, seeds of mosses, ferns, &c. are found to vegetate freely; while, if sown in soil, they might, from their minuteness, be liable to be too deeply buried.

According to Mr Limburn, electricity has a powerful influence in accelerating the vegetation of seeds, on account of its connection with all transformations of organic substances, either as cause or effect. Dr Carpenter, entertaining the same views, remarks that, "when chemical decomposition takes place, electricity is always developed," but suspects that in some instances it may be absorbed again by the new state of the compound. The influence of different coloured glass on the germination of seeds has been successfully experimented upon by Dr Horner of Hull, M. Payen, and others, who arrived at the conclusion that the violet or de-oxidising colour produces similar chemical effects to the negative or alkaline pole, while red produced the acid or opposite effect by the retention of the oxygen. Alkalies were successfully employed by M. Maltuen, who found that seeds vegetated sooner when placed at the negative pole of a galvanic battery than at the positive or acidified pole. Seeds enclosed by him in phials of acids and alkalies were found to germinate much quicker in the latter; while in the former they vegetated much slower, and sometimes not at all.

## § 2.—CROSSING OR HYBRIDISING.

We have elsewhere stated that most plants originated from seeds resemble their parents in

a very striking degree, although occasionally deviations of greater or less importance occur—sometimes, no doubt, naturally, and of late years much oftener by design. The true cause of such departures from legitimacy in nature, is, we believe, enveloped in obscurity. Man has it, however, in his power, under certain conditions, to create varieties *ad infinitum*, by the process of cross-breeding or hybridising—a process requiring great nicety in the performance, and a thorough knowledge of the physiological structure of plants. The old philosophers had some slight idea of sexuality in plants, and Pliny somewhere says, “All trees and herbs are furnished with both sexes;” but nothing definite appears to have been known until Sir Thos. Millington and Nehemiah Grew, in or about 1676, clearly established the fact. It is true, Malpighi, Cæsalpinus, and others, laid claim to priority in the discovery; but, in alluding to this circumstance, Dr Lindley remarks, “I see nothing so precise in their works as we find in the declaration of Grew, ‘that the attire (meaning stamens) do serve as the male for the generation of the seed.’” It would also seem, from a very curious passage in the Book of Deuteronomy, that the Jewish lawgiver was well acquainted with the phenomena of hybridisation, and with the danger of deterioration attendant on its being allowed to proceed indiscriminately among cultivated esculents: “Thou shalt not sow thy vineyard with divers kinds of seeds; lest the fruit of thy seed which thou hast sown, and the fruit of thy vineyard, be defiled.”—Deut. xxii. 9. Camerarius, so early as 1694, threw out some conjectures upon this subject. It was afterwards taken up by Bradley, in 1717, who proved the fact by producing hybrids artificially; by Linnæus, in 1744; and fully established by the experiments of Koelreuter, and since by a host of others. It is not a little strange that the great founder of the sexual system should have written a dissertation on the subject; and although he endeavoured to establish a doctrine which was true, the facts upon which he grounded his doctrine, in the estimation of modern botanists, were false. He even went so far as to allege that hybrid productions may occur between species belonging to different genera, and even to different families—a case, says the systematic botanist, of which no example that can at all be relied upon has ever yet been met with. That natural hybrids do exist is not denied by the most strenuous advocates of the purity of the sexes in plants, but they say that they are few in proportion to the number of vegetable species, and none exist which are the certain production of a union of species belonging to distinct families.

There are some who think otherwise, and contend that, if man can by art produce hybrids at will, by the connection between two species of the same genus, why should not nature have done the same over and over again since the creation of the world, and that by the very instruments which are the grievous marplot of every gardener who wishes to keep his favourite variety of melon, or his select early cabbage, pure and unadulterated? None knows the dif-

ficulty of preventing a species of adulterous intercourse from taking place amongst certain families of plants better than the enthusiastic hybridiser; for, with all his precautions, such things will happen. The fact is admitted in the case of diæcious plants, and conspicuously so in the numerous so-called species of willows. The doctrine held by some of the older botanists was recently almost revived by the hints thrown out by a learned gentleman at one of our scientific meetings in Edinburgh, much to the alarm of the younger, and perhaps more ardent than prudent students in botanical science, that there were originally only a few species formed, and that the rest of the vegetable world had arisen by hybridisation. The willow and the carex have been sore stumblingblocks to botanists: either of them may ask the first botanist that comes his way, “Pray, sir, what is a species?”

“Plants agree,” says the author of the “Suburban Horticulturist,” “with animals in the offspring when it is reared from seed bearing a general resemblance to the parent; but as in every family the children of the same parent differ individually in features, temper, disposition, &c., so among seedling plants, from the same seed-pod no two plants will be found exactly alike, and some will occasionally differ considerably from all the rest. Nevertheless, it is an undoubted fact that all seedling plants not only possess the character of the species from which they have sprung, but even, in by far the greater number of cases, some of the peculiarities of the individual. The seeds of any kind of cultivated apple, for example, will produce plants, the fruit of all of which will more or less resemble that of the parent, though, perhaps, some one or two among a hundred may be considerably different. Hence, by selecting from beds of seedling plants those which are in any way remarkably different from the rest, new varieties are procured; and till within the last half-century, when cross-breeding began to be practised by gardeners, this was the only way in which an improved variety of any species of plant was procured. If the seeds of varieties did not produce plants closely resembling their parents, how could all the improved varieties of culinary, agricultural, and floricultural plants be perpetuated? That the same law which governs herbaceous plants holds good in trees and shrubs cannot be doubted; and if the seeds of a variegated tulip are more likely to produce plants which shall have variegated flowers than those of a tulip with only one colour, so, we should say, the berries of a variegated holly are more likely to produce plants with variegated leaves than those of a green-leaved holly. If this law did not hold good in ligneous as well as in herbaceous plants, how are we to account for the different varieties of *Hibiscus syriacus* coming true from seed?”

*Advantages of hybridisation.*—By this process man is enabled to change the character and quality of flowers, and of fruits. The colours and symmetry of the former may be changed, or made more perfect, and the size, form, and flavour of the latter may be much improved, by a judicious selection of the parents called into action. Indeed, by this process man

possesses the power of modifying the works of nature, and rendering them better adapted to his wants and wishes. What would our gardens now be, were it not for the hundreds of beautiful flowers produced by this means, as well as the many superior fruits produced in a similar manner? The families of roses, azaleas, rhododendrons, pelargoniums, fuchsias, and hosts of others, bear evidence of this; while the improved kinds of pears, apples, strawberries, peaches, &c., give a still more conclusive corroboration. By this process the races of fruits and of culinary vegetables have been brought as near to perfection as it is, perhaps, possible to bring them; and it is more than probable that wheat, corn, barley, &c. are capable of being yet greatly improved if sufficient pains were taken with them. Nay, even the timber trees of our forests, which are subject to the same laws, are capable of a like improvement.

*The laws of hybridisation, or cross-breeding.*—“The species to be experimented on must be nearly related. The apple will not cross with the pear, nor the gooseberry with the currant.”—*Keith*.

M. Decandolle says, “that hybrids resemble the female parent chiefly in the leaf and stem, and the male parent chiefly in the flower and organs of fructification.” Professor Lindley reverses this order, which has led Keith to remark that the resemblance may have been found to be sometimes the one way, and sometimes the other. The Hon. and Rev. W. Herbert thinks, from what he saw in Amaryllides, that in hybrids the flowers and organs of reproduction partake of the character of the female parent; while the foliage and habit, or the organs of vegetation, resemble the male. “Hybrids may be fertilised, however, by the pollen taken from one of the parents, and then the offspring assumes the character of that parent.”—*Balfour*.

Further, on this very interesting subject Dr Lindley remarks, in “Theory of Horticulture,” that “if the pistil of one species be fertilised by the pollen of another species, which may take place in the same genus, or if two distinct varieties of the same species be in like manner intermixed, the seeds which result from the operation will be intermediate between its parents, partaking of the qualities of both father and mother. In the first case, the progeny is *hybrid*, or mule; in the second, it is simply *cross-bred*. In general, cross-breeds are capable of producing fertile seed, and thus of perpetuating one of the species from which they sprang. Hybrids, on the contrary, are often sterile, and therefore incapable of yielding seed. Reasoning from a few facts, and from the analogy of the higher orders in the animal kingdom, it has been believed that all vegetable hybrids are sterile; and when sterility is not the consequence of the intermixture of two species, it has been thought that such species are not naturally distinct, however different their appearance. But facts prove that undoubted hybrids *may be fertile*; and when we consider that plants are not analogous to the higher orders of animals, but to the lowest, concerning whose habits we know nothing whatever, it is obvious that no

analogical inferences can be safely established.”—(Vide Mr Anderson’s views at the end of the article.)

*Duration of hybrids.*—“Hybrids are fertile only till the third or fourth generation, when they revert ultimately to the type of one of the parents.”—*Keith*. “When cross-breeding is effected between what are considered different species, the offspring is a mule, or hybrid, which, in most cases, is incapable of maturing seeds, and generally, in the course of a few years, degenerates, or reverts to its original parentage. There are, however, instances of mules, or true hybrids, producing fertile seeds, from which plants have been raised, partaking of all the characters of the parent hybrid plant,” as in the case of some of the Cacti.—*Sub. Hort.*

*Uncertainty in propagating hybrids even otherwise than by seed.*—“It would appear, from the case of the *Cytisus adami*, or purple laburnum, that a true hybrid or mule cannot always be propagated with certainty, even by portions of the plant, or by what is called extension, since it never can be certain whether the portion taken off for propagation will produce the mule or one of the parents. As it is uncertain what are and what are not very distinct species, many of the plants originated by cross-breeding, and considered mules, may in reality not be so, and may consequently prove permanent and improved varieties.”—*Idem*. In this extraordinary tree the foliage is sometimes that of the common laburnum, sometimes of the purple *Cytisus* (*C. purpureus*), and sometimes intermediate between the two. The origin of this anomalous tree is not believed to have been from seed produced by the ordinary process of cross-breeding, but by some accidental mixture of the cellular tissue.

*The difference between propagating by seed and propagating by any other mode is very great.*—In propagating by seed, the species or variety in the abstract is propagated; while by all the other modes practised by gardeners the species or variety is continued without alteration in character, by an extension of the parts of the original tree or plant. Thus, a Hawthornden apple of 1852 is not a new plant, but only a portion of the original tree continued by the process of extension, carrying with it its habits and properties. Were we to sow the seeds of variegated plants, or of weeping oaks, ashes, or elms, few of the progeny, if any, taking it as a general rule, would exhibit the variegated or pendulous characters of their parents; and hence the necessity of continuing these varieties by budding, grafting, &c. On the same principle, were we to sow the seeds of any of our best apples, pears, plums, &c., the chances of obtaining from their seeds improved varieties, or even such as are equal to the parents, would be few indeed; we, therefore, are compelled to continue them by other means than from seeds. There are, however, exceptions to this rule, as in the case of the pendulous or weeping oak at Moccas Court, many of the acorns of which, when sown, produce plants very similar to the original; and we recollect having pointed out to us by the Duc d’Aremberg a splendid purple or copper-coloured

beech in his grounds at Enghien, which produced a considerable proportion of plants from seeds closely resembling the parent, while other trees of the same age and size in the same grounds produced invariably plants having green leaves, and in all respects like the common beech. In regard to the aptitude of fruit trees to produce plants from seed slightly removed in quality from the tree from which the seed was taken, we may mention the golden pippin apple and the green-gage plum, which often do produce plants whose fruit is as little different from the originals as that of the progeny of the wild plum or crab apple is different from the trees from whence the seeds were gathered. It should, however, be remarked, that as these two fruits are amongst the very best of their class, and may have taken many generations to have brought them to their high condition, it is possible that it may take as many more to reduce them in quality to their original or natural state. The circumstance also strongly favours the theory laid down by Dr Van Mons in the "Journal d'Agriculture des Pays Bas," of Mr G. Lindley in "Guide to the Orchard," both elsewhere referred to, as well as that of most cultivators who have made the propagation of improved fruits and plants their study. The practice of our best seed-savers is to save seed only from plants in the highest state of perfection, and in the highest state of culture; and by this means they continue to us not only what are called species, but varieties also, little changed from the plants from which the seeds were taken; and by this means only can we continue annual and biennial plants, as well as many of greater longevity, although we cannot depend on this mode in all cases with the same degree of certainty that we can on the various modes of propagating by extension—namely, by cuttings, division of the plant, grafting, budding, &c.

However much the systematic botanist may be discomposed by the production of hybrids, or of cross-bred plants, the florist, pomologist, and gardener have much cause to rejoice; for by this process they all have gained a triumph over nature, which, according to her greatest advocates, she could hardly have effected herself. The happy results of the late Mr Knight, in the production of some of our very finest fruits, and of our best pease, and other culinary vegetables, is of itself sufficient proof of the great utility of the process. We are told by botanists that hybrids are fertile only to the third or fourth generation. How can this doctrine be reconciled with the case of Knight's marrowfat pea, which has continued to reproduce itself over the whole kingdom for upwards of thirty generations, and is likely to continue as long? For the interesting experiments of Mr Knight, *vide* the "Philosophical Transactions from 1789 to 1820," and various papers in "Horticultural Society's Transactions, first series," &c.

"The power of hybridising," Dr Lindley remarks, "appears to be far more common in plants than in animals. There is scarcely a genus of domesticated plants in which this effect cannot be produced by the assistance of man.

It is, however, in general, only between nearly allied species that this intercourse can take place, those which are widely different in structure and constitution not being capable of any artificial union. The cause of the sterility of mule plants is at present unknown. Sometimes, indeed, a deficiency of pollen may be assigned; but in many cases there is no perceptible difference in the healthiness of the structure of the fertilising organs of a mule plant and of its parents." Even the very comprehensive anatomical observations of Professor Henslow have thrown no light upon the subject, for he could detect no appreciable difference between the condition of the stamens and pistil of the hybrid or its parents. Amongst the instances of fertile hybrids found wild in nature, Dr Lindley states the following as remarkable cases: "The *Cistus ledon* constantly produced between *C. monspeliensis* and *laurifolius*, and *Cistus longifolius* between *C. monspeliensis* and *populifolius*," observed by Mr Bentham in a wood near Narbonne. "The same acute botanist ascertained that *Saxifraga luteo purpurea* of Lap., and *S. ambigua* of Decandolle, are only wild accidental hybrids between *S. aretioides* and *calyciflora*. Gentianas, having a similar origin, have also been remarked upon the mountains of Europe. It is difficult not to believe that a great number of the reputed species of *Salix*, *Rosa*, *Rubus*, *Aquilegia*, and other intricate genera, have also had a hybrid origin."

It has been stated above, as the opinion of some, that hybrid varieties cease to reproduce themselves after the third or fourth generation. We have already instanced Knight's marrowfat pea, &c., as an exception to this rule; and on looking over some old seed-lists—that of Gordon, for example, one of the earliest seedsmen established in Edinburgh—we find in his "Dictionary," published in 1774, the names of many of our kitchen-garden seeds identical with those of seed-lists of 1852: that any change for the worse has taken place in them, we have no right to suppose. True species, in the strict sense of the word, they cannot be; hybrids, therefore, they must be. The same may be said of our cereal plants, some of which have, no doubt, existed for centuries. It appears, therefore, pretty clear that hybrids may continue in a fertile state for ages, without much, if any, deterioration. Had hybrids in a state of nature been as long and as closely watched, it is probable that our list of recognised individuals would be much larger than it is at present. The following explanation of the law which governs this case is given by Dr Lindley: "It is a general law of nature that seeds will perpetuate a species, but not a variety; and this is no doubt true, if rightly considered; and yet it may be urged, if this be so, how have the varieties, well known to gardeners and agriculturists for many years, been unceasingly carried on from generation to generation without change? The long red and round white radishes of the markets, for instance, have been known from time immemorial in the same state in which they now exist. The answer is thus: A species will perpetuate itself from seed for ever under any cir-

circumstance, and left to the simple aid of nature ; but accidental varieties cannot be so perpetuated—if suffered to become wild, they very soon revert to the form from which they originally sprung. It is necessary that they should be cultivated with the utmost care ; that seed should be saved from those individuals only in which the marks of the variety are most distinctly traced ; and all plants that indicate any disposition to cast off their peculiar characteristics should be rejected. If this is carefully done, the existence of any variety of annual or perennial plant may be undoubtedly prolonged through many generations."

The following concise and excellent rules are given in the "Cottage Gardeners' Dictionary," regarding the process and effects of hybridising : "Hybridising, strictly speaking, is obtaining a progeny between two different species, by fertilising the stigma of one with the pollen of another ; and cross-breeding is obtaining a progeny between varieties of the same species. The progeny of hybrids cannot produce seed, but cross-breeds are fertile." The following may act as a guide to the raiser of varieties : "The seed-vessel is not altered in appearance by impregnation from another plant ; therefore, no hasty conclusion of failure is justified by that want of change.

"The colour of the future seed out of that first hybridised seems to be most influenced by the male plant, if its seeds and flowers are darker than those of the female. Captain Thurtell, from his experiments on the pelargonium, found the colour and spot of the petals to be more influenced by the male than by the female. Indeed, all experience proves that the progeny usually, though not invariably, most resembles in colour the male parent. Large stature and robustness are transmitted to the offspring by either parent, but Mr Knight generally found the most robust female parent producing the finest offspring. Captain Thurtell, from lengthened observation, has ascertained that the form of the petals follows most closely that of the female parent. Mr Knight says that the largest seed, from the finest fruit that has ripened earliest and most perfectly, should always be selected. In stone fruit, if two kernels are in one stone, these give birth to inferior plants. The most successful mode of obtaining good and very distinct varieties is to employ the pollen from a male flower grown on another plant than that bearing the female parent. To avoid previous and undesired impregnation, the anthers of the female parent, if they are produced in the same flower with the pistils, must be removed by a sharp-pointed pair of scissors, and the flower enclosed in a gauze bag to exclude insects, until the desired pollen is ripe. Another effectual mode of avoiding undesired impregnation, is bringing the female parent into flower a little earlier than its congeners, and removing the anthers as above described : the stigma will remain a long time vigorous if unimpregnated. When double flowers are desired, if a double flower should chance to have a fertile anther or two, these should be employed for fertilisation, as their offspring are almost sure to be double."

VOL. II.

Besides the opinions already stated, others believe the sterility of hybrids to arise from a deficiency of pollen or fertilising dust ; while the highest authority we can quote (the late Dean of Manchester) was of opinion that it arises from the juices of each individual type being inadequately adapted to yield the exact proportion of what is wanted for the pollen of its kind ; and that, wherever that adaptation is perfect, a perfect offspring is produced. "Where it is not perfect," he says, "an inadequate or a weak fertilisation takes place. It is further to be observed that there is frequently an imperfect hybrid fertilisation, which can give life, but not sustain it well. There are several crosses which I have frequently obtained, but could not raise the plants to live for any length of time." He states various crosses which he effected, but lost the plants so produced while they were yet young, "on account," as he says, "of *his soil being very uncongential to them.*" but which, he believed, under more fortunate circumstances, would have been saved. Such crosses sometimes are a hundred times more delicate in their first stage than natural seedlings. "In these cases, I apprehend," says the same authority, "that, although the affinity of the juices is sufficient to enable the pollen to fertilise the ovule, the stimulus is insufficient, the operation languid, and the fertilisation weak, and inadequate to give a healthy constitution. It has been generally observed that hybrid fertilisation is slower than natural fertilisation, and that often a much smaller number of ovules are vivified. The same cause probably operates in that respect ; the affinity not being perfect, the necessary ingredients are attracted by the pollen less readily and insufficiently, and by many of the grains not at all."

*Seedlings originated by unknown causes, or sports of nature.*—The laws of nature are, upon the whole, uniform, and seldom are they violated. In endeavouring to trace the first origin of our longest established cultivated culinary vegetables and fruits, a degree of obscurity appears to envelop the subject. If all our apples and pears originated from the *Pyrus malus* and *Pyrus communis*, and our cabbages and pease from *Brassica oleracea* and *Pisum sativum*, as we are taught to believe, when, and by what means, it may be asked, did the first remove from the originals to an improved variety take place ? This is a problem we have never met with any satisfactory solution of. The original plant in either case could not be a hybrid, for there was no other to hybridise it with. High cultivation was very unlikely to be the cause either ; for, at the period of their first appearance, we may presume, cultivation was little attended to. Were they accidental sports, as the weeping ash and weeping oak and various others are said to have been ? If so, this process must have been going on from a very remote period, as we are informed that twenty-two sorts of apples, and thirty-six kinds of pears, were known to the Romans in the days of Pliny. The Romans knew nothing of hybridising, nor was it well known to the moderns till about the beginning of the present century. We can readily

admit that natural hybridisation may have been going on since the first tree in each of these cases came into existence; but how came they to exist in the first instance? If nature has been sporting in this way for so long a period, she will, no doubt, continue to do so till the end of time. If she has done so in the case of our fruits and culinary vegetables, may she not have been doing so in the case of all other plants and trees? and, therefore, may not hundreds of these, recognised now as species at least, have been so produced? Is not the same law going on yearly in the case of nine-tenths of what are called our improved vegetables? for it is certain that even that proportion is not produced by actual artificial cross-breeding; and the same thing is also going on in the case of our improved fruits. By what other means were the Hawthornden, Claygate pearmain, scarlet-nonpareil apples, &c., produced? The former, now in the last stage of decay, was a founding in the garden from whence it takes its name; and of the two latter—the one was found wild, in a neglected hedge-row, at Claygate, near Claremont, and the other in the garden of a petty public-house in the village of Esher, and within a mile and a half of each other. Many other instances could be given in support of this sportive freak of Dame Nature's. As these fruits are amongst the most valuable of their kind, we need not despair of being provided with still more improved fruits to the end of time, and that without the intervention of artificial means.

The weeping ash, set down as a sport of this kind, appears to be cursed with that sterility which some attribute to mules and hybrids, as it produces no seed capable of reproducing itself in its pendant form. But the truth is, the original weeping ash, from which we presume every plant of the kind in Europe has been derived, is a female tree, so that, when the original or any of its progeny has produced seeds, it has been in consequence of their flowers having been fecundated by those of some male tree in its vicinity. The Moccas Court weeping oak is more fortunate, as it produces from seeds almost all the young plants with drooping branches. Whatever may have been the origin of the golden pippin apple and green gage plum, they, as already remarked, produce plants from seed in general differing as slightly from themselves as the produce of a crab-apple or wild plum differs from the trees that produced them. The seeds of the cultivated cabbages and pease are well known to produce a progeny in all respects like their parents. Well may we say with the Psalmist, "O Lord, how wondrous are thy works! in wisdom hast thou made them all."

However diversified opinions may be upon the subject of hybridising, or cross-breeding among plants, of the vast importance of it none can doubt. Those interested in the matter should consult the valuable papers by the late Dean of Manchester, the Hon. and Rev. W. Herbert; Mr Thwaites' interesting remarks in the "Annals of Natural History," i. N. S., p. 168; or Lindley's works, &c. &c.

The former of these talented writers spent a long lifetime in the study of this particular

department of vegetable physiology, and arrived at conclusions of themselves original, if not substantially correct; but as to their correctness, for ourselves, we have not a shadow of doubt. This opinion is greatly strengthened by the declaration of Professor Lindley, who says of the paper from which the following quotation is taken, "*that it is the best paper we possess upon the practical value of the facts elicited by hybridising.*" "I will therefore state briefly and humbly," says the Dean, "what is the general basis of my surmises as to the diversification of vegetables, to which that of animals must be in a certain degree analogous. We know that four races of men have branched out of one stock—the white, the black or African, the brown or Asiatic, and the red, with various subdivisions of aspect amongst them; and we know nothing of the mode or time in which those diversities arose. Revelation and history are equally silent on those facts. They must have occurred very early. We are equally in the dark as to the races of dogs. Old writers allude to different kinds of dogs, and we do not know when or how any one of those we possess originated; and the same may be said in respect to the origin of languages. From these facts I draw this inference, which seems to me incontrovertible, that a course of change was in operation in the early ages after the Deluge, which had ceased, or was greatly diminished, before the era at which our knowledge of events began to be more precise, and handed down by writing. I shall be told that these different races of men breed freely together, and that these dogs intermix and produce mongrels also, and we see thereby that they are only varieties of one kind. Granted: I entertain no doubt of their having respectively descended from one pair of created individuals. But how do you prove to me that the cat, lynx, tiger, panther, lion, &c., did not descend from one created pair? I am rather inclined to think that they did (but this is only surmise), and even the horse and the ass from one created pair; and I am quite unable to believe that the several sylvæ of the wren family, some of which can with difficulty be distinguished except by the proportions of their quills, and which have, nevertheless, very diverse habits, notes, and nests, were created separately and specially; and when I look to the vegetable races, I am still more unwilling to assent to the assertion, that every plant which this or that botanist has called a distinct species, or even a distinct genus, had a special creation in the period before the sun and moon shone upon this world, when God created vegetables. Upon what authority is such an assertion made? Upon none but the dictum of those who are pleased to inculcate it. Upon what ground is it made? Upon none that will bear investigation;—upon a rash assumption that everything cross-bred is sterile, and that, if the offspring is sterile, the parents are thereby proved to have been descended severally from the Creator. In the first place, the fact is even false as to animals. Buffon records an instance of the fertility of a mule. I have seen that which I am satisfied was a hybrid between a bitch and a fox which was the father of

many puppies. But if the fact were positively true, how is it to be proved that the constitution and frame may not have undergone such changes in the diversification as to prevent intermixture? If I can show that in one genus of plants cross-breeding is not only easy, but more easily obtained than fertility by the plants' own pollen, and that in others, so closely allied to it as to make it a question whether they are not sections of one genus, cross-breeding cannot be effected generally, and in no case easily; that in some genera of plants many or all the cross-bred varieties are fertile, and in others nearly allied thereto, all, or almost all, are sterile,—the assertion that the races of *canis* or dog must have had one origin because their crossed produce is fertile, and the races of *felis*, from the cat to the tiger, must have had separate origin because their crossed produce is sterile (supposing the fact to be true, which is not ascertained), must fall to the ground. The only thing certain is, that we are ignorant of the origin of races, that God has revealed nothing to us on the subject; and that we may amuse ourselves with speculating thereon, but we cannot obtain negative proof—that is, proof that two creatures or vegetables of the same family did not descend from one source. But we can prove the affirmative, and that is the use of hybridising experiments, which I have invariably suggested; for if I can produce a fertile offspring between two plants that botanists have reckoned fundamentally distinct, I consider that I have shown them to be one kind; and indeed I am inclined to think that, if a well-formed and healthy offspring proceeds at all from their union, it would be rash to hold them of distinct origin. We see every day the wide range of seminal diversities in our gardens. We have known the dahlia, from a poor single dull-coloured flower, break into superior forms and brilliant colours; we have seen a carnation, by the reduplication of its calyx, acquire almost the appearance of an ear of wheat, and look like a glumaceous plant; we have seen hollyhocks in their generations branch into a variety of colours, which are reproduced by the several descendants with tolerable certainty. We cannot, therefore, say that the order to multiply after their kind meant that the produce should be precisely similar to the original type; and if the type was allowed to reproduce itself with variation, who can pretend to say how much variation the Almighty allowed? Who can say that His glorious scheme for peopling and clothing the earth was not the creation of a certain number of original animals and vegetables, predestined by Him, in their reproduction, to exhibit certain variations which should hereafter become fixed characters, as well as those variations which even now frequently arise, and are nearly fixed characters, but not absolutely so, and those which are more variable, and very subject to relapse in reproduction?"—*Jour. of Hort. Soc.*

For the following remarks on this very interesting subject we are indebted to our excellent friend Isaac Anderson, Esq., S.S.C., one of the most scientific, energetic, and successful hybridisers of the present day:—

"To go fully into the theory and practice of

hybridising, a volume might be devoted to the subject, and still leave it unexhausted. To start with the beginning would be to start with creation itself—in fact, nature, as conjectured by Linnæus, was occupied by but few original types of the innumerable vegetable forms which have been transmitted to us. How these few first types, if that great authority was right in that belief, have become varied and multiplied, from classes to tribes, from tribes to genera, and from genera to species and endless varieties, belongs to those mysteries of Divine agency which set all inquiry at naught, and upon which it were equally unprofitable and presumptuous at the present time to speculate. For who, in treating of such a science, dare invade a field where the Omnipotent invoked no aid from man—ere yet, indeed, man was; while the sun and skye influences, and the whole host of insectivorous races, now extinct, were perhaps but *parts* of the agencies and instrumentalities by which,

'With herbs, and plants, and fruitful trees,  
The new-formed globe He crowned,'

and made it fit for man's use and habitation? Who can speculate now on those atmospheric properties, 'instinct with life,' under whose influence man grew and increased in strength, till the span of his existence extended to near a thousand years—when there were giants on the earth—

'When man was in stature as tow'rs in our time,  
The first-born of Nature, and, like her, sublime?'

A life-giving and life-sustaining Spirit breathed the will, and effected the purposes of the Creator. Perhaps a larger portion and a more genial form of electricity than now obtains, may have imparted a principle of higher vitality to the air, and through that medium have communicated a stronger impulse, and more enduring energies, to both animal and vegetable life. This may or may not have been; certain it is that a change has taken place. Since the Deluge, the vital forces have been greatly weakened. Man, since then, has scarce lived a tithe of his former term; and the vast exhumations of fossil flora bespeak an exuberance and variety of vegetation, in temperate zones, that have no parallel at the present day even in tropical regions.

"Why do we now see natural families with *genera* whose affinities are indisputable, and yet in their extreme links so dissimilar? Perhaps no one of the larger family of plants has its intermediate connections better filled up than the *Eriaceæ*, yet how many links are wanting in the chain between the *Rhododendron arbooreum* of India, of 40 feet high, and the *Chamaedon* (Azalea) *procumbens* of our own Highland mountains, of only 4 inches, or some of the smaller heaths! Though all allied, how many links are there between the various tribes, and even genera, of this most interesting family; e. g., between the *Vacciniæ* and the *Pyroleæ* as separate tribes, or between the *Rhododendron* and the *Menziesia*, as separate *genera*. The scarcely-known elevated plateaus and ridges of the Andes have already yielded up some kindred races in the *Bejaria* and *Thibaudia*; and who can tell if, when better explored, many more links wanting may not be supplied? Travel-

lers have observed examples of the *Rhodorea* on the high mountains of the Hawaiian group of isles in the Pacific, and in Manilla, Malacca, and other islands of the Indian Ocean, as well as in North-west America, yet unknown to gardens. Thirteen species of this family have been observed on one hill in Borneo alone, and at least half that number in Java. Dr Hooker has reclaimed about thirty species from the Sikkim ranges of the Himalaya, and of such varied growth and aspect, that our thymes may represent the one group, and our oaks the other—a tiny thing (*R. nivale*) creeping on the ground at 18,000 feet above the sea, and another (*R. bartatum*) attaining a stature of 60 feet.

“All these discoveries have done much to fill up many gaps in this widely-distributed family, and the discoveries of future travellers may fill up many more.

“But how many tribes, genera, and their species, are for ever lost! Man inhabits but the *disjecta membra* of a former world. With continents, now beneath the ocean, are buried—perhaps for ever lost—genera which, if restored, might supply all those gaps which leave existing races so wide apart. But nature has left materials to work upon, and the art and ingenuity of man may do much to fill up the blanks.

“A very eminent nurseryman—the late Mr Cunningham of Comely Bank—so far filled up one link of this order, by hybridising the *Phylodoce* (*Menziesia*) *cerulea* with the *Rhodothamnus chamæcistus*, and producing therefrom the beautiful (so-called) *Brianthus erectus*. But the parents were too far remote, and the progeny—a proper mule—is consequently barren. It is somewhat singular, that while the *M. cerulea* will cross with the *Rhodothamnus chamæcistus*, the latter will not be crossed with it. It was the *Menziesia* that bore the seed from which the so-called *Brianthus* was raised. I speak from my own experience in this matter, having, before Mr Cunningham's experiment was known, attempted unsuccessfully to cross the *Rhodothamnus* with the *M. Crerulea*, though I have since succeeded in ripening seeds and raising plants from the cross inverted. These I sowed on 18th June 1850, and on 10th September four young plants had come through.

“To those who would attempt the hybridising or cross-breeding of plants, I will now offer some suggestions for their guidance.

“It is an *essential* element to success that the operator be possessed of indomitable *patience, watchfulness, and perseverance*. Having determined on the subjects on which he is to operate, if the plants are in the *open ground*, he will have them put into pots, and removed under glass, so as to escape the accidents of variable temperature—of wind, rain, and dust, and, above all, of insects. A greenhouse fully exposed to the sun is best adapted for the purpose, at least as regards hardy and proper greenhouse plants.

“Having got them housed, secure a corner where they are least likely to be visited by bees or other insects. The plants which are to yield the pollen, and the plants which are to bear the seed, should be both kept in the same temperature; but where this cannot be managed,

pollen from an outside plant, in *genial* summer weather, may be used, provided it can be got; for there is a class of insects which live exclusively on pollen, and devour it so fast after the pollen vessels open, that, unless the plant is under a hand-glass (which I would recommend), it is scarcely possible to get any pollen for the required purpose. To secure against chances of this nature, a sprig with opening bloom may be taken and kept in a phial and water inside, where it will get sufficient sun to ripen the pollen. But here, too, insects must be watched, and destroyed if they intrude. An insect like, but smaller, than the common hive bee, which flits about by fits and starts, on expanded wings, after the manner of the dragon-fly, is the greatest pest, and seems to feed exclusively on pollen. The hive bee, the humble bee, and wasp give the next greatest annoyance. All these may be excluded by netting fixed over apertures from open sashes or the like. Too much care cannot be bestowed on excluding these intruders, whose single touch, in many cases, might neutralise the intended result; for the slightest application of pollen native to the parent plant is said by physiologists to supersede all foreign agency, unless, perhaps, in the crossing of mere varieties; and the truth of this observation consists with my own experience. Without due precaution now, the labour, anxiety, and watchfulness of years may issue in vexation and disappointment.

“As a further precaution still, and to prevent self-fertilisation, divest the blooms to be operated on not only of their anthers, but also of their *corollas*. Remove also all contiguous blooms upon the plant, lest the syringe incautiously directed, or some sudden draft of air, convey the native pollen, and anticipate the intended operation. The corolla appears to be the means by which insects are attracted; and though, when it is removed, the honey on which they feed is still present, they seem puzzled or indifferent about collecting it; or if, haply, they should alight on the dismantled flower (which I never have detected), the stigma is in most cases safe from their contact.

“It will be some days—probably a week or more, if the weather be not sunny—ere the stigma is in a fit condition for fertilisation. This is indicated in many families, such as *ericaceæ, rosaceæ, scrophularinæ, aurantiaceæ, &c.*, by a viscid exudation in the *sutures* (where these exist) of the stigma, but generally covering the entire surface of that organ. In this condition the stigma may remain many days, during which fertilisation may be performed; and this period will be longer or shorter as the weather is sunny, or damp or overcast.

“In certain families, such as the *Malvaceæ, Geraniaceæ, &c.*, where the stigma divides itself into feathery parts, and where the viscid process is either absent or inappreciable by the eye, the separation of these parts, the bursting of the pollen, the maturity of the stigma, and all which a little experience will detect, indicate the proper time for the operation, sunny or cloudy weather always affecting the duration of the period during which it may be successfully performed.

“As to the proper *time and season* best adapted

for such experiments, a treatise might be written; but here a few remarks must suffice.

"As for the *season of the year*, from early spring to midsummer I would account the best period; but, as I have just observed, I regard all cold, damp, cloudy, and ungenial weather as unfavourable. On the other hand, when the weather is *genial*, not so much from sun heat as at times occurs from the atmosphere being moderately charged with electricity, when there is an elasticity, so to speak, in the balmy air, and all nature seems joyous and instinct with life, this, of all others, is the season which the hybridist should improve, and above all if he attempt muling.

"The hybridist should be provided with a pocket *lens*, a pair of wire *pincers*, and *various coloured silk threads*.

"With the *lens* he will observe the maturity of the *pollen* and the condition of the *stigma*, whether the former has attained its *powdery*, and the latter (if such is its nature) its *viscous* condition. If he find both the *pollen* and the *stigma* in a fit state, he will, with the *pincers*, apply an author with ripened pollen, and by the gentlest touch distribute it very *thinly* over the summit of the *stigma*. The operation performed, he will mark it by tying round the flower-stalk a bit of that particular coloured *silk thread* which he wishes to indicate the particular plant which bore the pollen, and at same time tie a bit of the same silk round the stem of the latter, which will serve till recorded in a note-book, which should be kept by every one trying experiments on a large scale.

"It would be out of place here to give even a general outline of the parts of flowers, to show how these differ the one from the other in various tribes of plants. The experimenter, if he is not a botanist, and even though he is partially acquainted with the science, must, from books and observation, make himself familiar with the various organs, male and female, of each separate family of plants on which he means to work, otherwise he will be often puzzled where to find them, or even to distinguish the one from the other.

"As for the *time of the day*, it may be done almost any hour from 9 A.M. till 4 o'clock P.M., and with equal success. My other avocations have often limited me to earlier and later hours; but I would suggest from ten till two o'clock as the best time of day, always preferring fair, genial, and sunny, to chill, damp, or cloudy days.

"On recurring to my note-book for 1850, I find a very favourable state of atmosphere occurred in the beginning of March of that year, when I crossed the *Phyllococe (Menziesia) cærulea* with the *Rhodothamnus (Rhododendron) chamæcistus*, sowed on 18th June that year, as above noticed. At this time, too, I succeeded in crossing the above *rhodothamnus* with a large-leaved white-flowered *Nepal species of rhododendron*, the blooms of which were 2 inches across the limb. But though I ripened that season three or four pods of this last cross, each pod of seed beautifully ripened, all of which I sowed, I cannot assert that any one seed vegetated; and though it is now nearly three years since the seeds were sown, I

still preserve the seed-pot. And I may remark here, from my own experience, that two years is not too soon to despair of vegetation even of seeds from abroad, on which, of course, no cross had been effected.

"Few seasons have occurred so favourable for the hybridist as the short interval in the beginning of March 1850, above alluded to. Singularly enough, happening to visit Lord Rosslyn's gardens at Dysart House, on the 1st of June that year, with the late Professor Dunbar, Mr McIntosh (the author), and Mr Sprott, I observed the above *rhodothamnus* marked as crossed. I found it had been crossed at the above period, and with *Rhododendron arboreum*! The seed-pods were then fully swollen, and approaching maturity; but I have not heard that anything has come of them.

"It is quite unnecessary to offer any directions as to the results to be effected. If it is desired to reproduce the larger, finer formed, or higher coloured bloom of a plant having a tall, straggling, or too robust a growth, or having too large or too coarse foliage in a plant without these drawbacks, I need not suggest to select, in another species of the same family, a plant of an opposite character and properties—say of dwarf compact growth, handsome foliage, and free flowering habit; and if such can be obtained, work with it, making the latter the seed-bearer. Or, if it be desirable to impart the fragrance of a less handsome kind to another more handsome, I would make the cross upon the latter. I cannot speak with certainty from my own experiments how far perfume may be so communicated; but I have some things far advanced to maturity to test it; and I entertain the hope that fragrance may not only be so imparted, but even heightened, varied, and improved. Or if it be desired to transfer all, or any valuable property or quality, from a tender exotic species to a native or hardy kind, work upon the latter; for so far as constitution goes, I agree with those who hold that the female overrules in this particular. I would offer this caution to those who wish to preserve the purity of certain flowers for exhibition, especially those having white grounds, not to cross such with high-coloured sorts. I once spoiled a pure *white* bloomed *Calceolaria* for exhibition by crossing it with a *crimson* sort; all the blooms on those branches where the operation had been performed, being stained *red*, and not the few flowers merely on which the cross was effected.

"In this note, already too long, I cannot further illustrate my remarks, by recorded experiments in the various tribes upon which I have tried my hand; but I cannot leave the subject without inculcating, in the strongest manner, the observance of the rules I have laid down to prevent vexatious disappointments. If any doubts arise about the cross being genuine or effectually secured, let not the seeds be sown. Three, four, five, and even six years, must oftentimes elapse with trees and shrubby things ere the result can be judged of; and if eventually it prove a failure, or even doubtful, it is worse than labour lost, inasmuch as it may mislead. If there is no great departure from the female parent, the issue is to be mistrusted. It is singular, if well accomplished, how much of both parents is blended

in the progeny. Gentlemen eminent as physiologists have read nature's laws in these matters a little differently from what my own humble experience has taught me, and assigned to the progeny the constitution and general aspect of the one parent, while they gave the inflorescence and fruit to the other. I have crossed and inverted the cross, and can venture to give no evidence on the point, except, perhaps, as to constitution, to which the seed-bearer, I think, contributes most. A well-managed hybrid should and will blend both parents into a distinct intermediate, inasmuch so as to produce often what might pass for a new species. If the leaning be to one more than another, it is probably to the female, though this will not always be the case.

"Again, it is asserted that a proper hybrid—i. e., one species which is crossed with another species, which is separate and distinct from it—will produce no fertile seeds. This does not accord with my observations. Dr Lindley has remarked very justly ('Theory of Horticulture,' p. 69), 'But facts prove that undoubted hybrids may be fertile.' My hybrid, *Veronica Balfouriana* (an intermediate between *V. saxatilis* and *V. fruticulosa*), seeds, I would say, more abundantly than either parent; and the progeny from its self-sown seeds I find to be of various shades of blue, violet, and red, rising in my garden, some having actually larger, finer, and higher-coloured blooms than the parent bearing the seed; and I am familiar with the same result in other things. Yet I am far from asserting fertility in the produce between two members of allied but distinct genera—such, for example, as in the *Briantus*, which I have found to be unproductive, whether employed as the male or female parent. As above conjectured, its parents were far too remote in nature's own arrangement. The hybridist has a field before him ever suggestive of new modes of acting. He may try, as I have done, what may be effected under various tinted glass. My persuasion is, that I varied from a pale yellow a pure white-grounded calceolaria, by placing the plants under blue-shaded glass, by which the sun's rays were much subdued. He may also apply chemical solutions to plants with ripening seeds. Nature, in producing, as it sometimes does, plants with blooms of colours opposite to those of the parent, must be governed by some law. Why may not this law be found out? For example, under what influences was the first *white fuchsia*, the *F. Venus Victrix*, produced, the purest yet of all the race, and the source from which all the whites have been derived?

"While I have necessarily confined the above remarks to things proper to the flower-garden, a wide and still more important field lies beyond. The late lamented Mr Knight of Downton did much in this way to improve our garden fruits and other esculents, and with a success that none else—so far as I am aware—has since attained. Why should not these efforts be extended to the improvement of agricultural as well as horticultural productions? Why not carry them into field and forest, to the creation of new, more useful, and more elegant forms? Nature is boundless, and its objects are endless, and this subject, of all others connected with

plants, the most engrossing and exciting. Rich results await the intelligent experimenter; but I would advise none to embark in the pursuit who has not sufficient leisure to devote to it, and, as I said before, who is not possessed of indomitable patience, watchfulness, and perseverance, with a fixed determination not to be fretted or discouraged by frequent failures.

"MARYFIELD, June 1853.

L. A."

### § 3.—PROPAGATION BY GRAFTING.

The art of grafting is so ancient, that anything connected with its origin is lost in the obscurity of ages. Theophrastus and other Greek authors speak of grafting as if it had been well known in their day; and Varro, a Roman writer, notices upwards of twenty modes as practised in his time. The late Professor Thouin enumerates above forty methods; and M. Louis Noisette some years ago published a description, with figures, of one hundred and thirty-seven. The most probable conjecture as to the origin of that variety of it known as inarching, is the accidental meeting of two branches from neighbouring trees, which, first by friction against each other till the bark of both branches became displaced, and afterwards by uniting, formed so perfect a junction, that when either was separated from its fellow, it became supported by the other. Of the origin of grafting proper, as well as of budding, we know little or nothing.

We have stated above that the varieties of grafting are very numerous. In this country these are divided into what may be called three distinct species—namely, grafting, budding, and inarching; while on the Continent no such distinction is observed. The French, for example, have no proper word to represent either, but use the general term *graffe* for all of them. Hence, *graffes par gemmes*—grafting by buds, or budding, &c.

The theory of grafting has been explained by Decandolle, in his "Physiologie Végétale;" by Mr G. Lindley, in "Guide to the Orchard;" Keith, in "Physiol. Botany;" Knight, Loudon, and others. On this subject the former says: "The shoots springing from the buds of the scion are united to the stock by the young growing albumen, and once united, they determine the ascent of the sap rising from the stock; and they elaborate a true or proper juice, which appears evidently to reascend in the inner bark. This sap appears to be sufficiently homogeneous, in plants of the same family, to be, in course of its passage, absorbed by the growing cellulæ near which it passes, and each cellule elaborates it according to its nature. The cellulæ of the albumen of the plum elaborate the coloured wood of the plum; those of the albumen of the almond, the coloured wood of the almond. If the descending sap has only an incomplete analogy with the wants of the stock, the latter does not thrive, though the organic union between it and the scion may have taken place; and if the analogy between the albumen of the scion and that of the stock is wanting, the organic union does not operate; and as the scion cannot absorb

the sap of the stock, the graft does not succeed." Mr G. Lindley, after referring to the circumstance that, in the stems of grafted trees or plants, the cellular tissue is found alive in the liber and medullary rays only, and that it is essential that those parts both in the scion and stock should be brought into contact, proceeds: "In regard to the medullary rays, these are so numerous, and so closely placed, that it is scarcely possible that a portion of one stem should be applied to another, without the medullary rays of both touching each other in many points. No care, therefore, is required to insure this, which may be safely left to chance. But in regard to the liber (or bark), as this is confined to a narrow strip in both stock and scion, great care must be taken that they are both placed as exactly in contact with each other as possible, so that the line of separation of the wood and bark should, in both stock and scion, be accurately adjusted. The success of grafting depends very much upon attention to this. But there are other reasons why this accuracy in adjusting the line between the bark and wood of the stock and the scion is so important. It is at that part that the roots of the latter pass downwards over the former; and it is also there that the substance called *cambium*, which serves as food for the young descending fibres, is secreted. It is obvious that the more accurate the adjustment of the line separating the wood from the bark, the more ready will be the transmission of young fibres from the one to the other; and that the less the accuracy that may be observed in this respect, the greater the difficulty in this transmission will be. Provided the stock and scion be of exactly the same size, the adjustment can scarcely fail to be accurate in the most unskilful hands: it is in the more common case of the scion being much smaller than the stock that this is to be more particularly attended to." Keith's remarks are even more clearly given: he says, "The whole of the art of artificial grafting is founded upon the capacity inherent in plants of uniting together by the stems in given circumstances and in a given mode. But the natural graft is always effected by means of the union of the liber of the respective stems composing it; so that the perfection of the art of grafting consists in applying the liber of the graft and stock together in such a manner as will most facilitate their incorporation; and hence the graft will not succeed, unless the two liber are brought into contact, and closely bound together. Nor will it succeed well, unless the plants engrafted have some natural affinity to one another, as that subsisting between the plum and cherry; in which, and in all other cases, the union is effected by means of a granular and herbaceous substance exuding from between the wood and bark, and binding and cementing together the stock and graft, though not uniting the former layers of wood."

Knight, in reference to the same subject, says: "It will be necessary that I describe the motion of the sap, as I conceive it to be at the period when grafts are most advantageously inserted. The graft first begins its efforts to unite

itself to the stock just at the period when the formation of a new internal layer of bark commences in the spring; and the fluid which generates this layer of bark, and which also feeds the inserted graft, radiates in every direction from the vicinity of the medulla to the external surface of the albumum. The graft is of course most advantageously placed when it presents the largest surface to receive such fluid, and when the fluid itself is made to deviate least from its natural course. This takes place most efficiently when a graft of nearly equal size with the stock is divided at its base, and made to stand astride the stock;" as in a variety of saddle-grafting invented by this eminent physiologist.

The principle on which all the operations in grafting, budding, and inarching are founded, according to Loudon, is dependent on the phenomena of the union of newly generated tissues, when in the act of being generated. "No union can take place between the parts of plants previously formed, but only when these parts are in the act of forming. Thus two shoots or branches may be selected, and by means of similar sections be most accurately joined, and placed under the most favourable circumstances for uniting; yet when the two are bound together, though a union do ultimately take place, not one particle of the existing tissue, at the time of grafting, becomes united with similar tissue brought in contact with it. Close contact is all that takes place with regard to these surfaces of the scion and stock, but a vital union only occurs when nascent tissues meet. The albumums of the *preceding year* never unite. The vital union is formed solely by the coalition of newly generated tissues, thrown out by such parts as have the power of generating them. This power does not exist in the heart-wood, nor in the outer bark, but only in the albumum, or rather in the substance imbedded between it and the inner bark, constituting the cambium. If the sections are placed against each other so as the inner barks coincide, the scion may perhaps derive an immediate supply of moisture; but it does so only in a mechanical way, and a piece of dry sponge might as truly be said to have formed a connection from its absorbing moisture, in consequence of its being placed on top of a stock, as the scion, that only takes up moisture as above mentioned. When, however, new tissue is formed by the parts of the respective sections, then, when the portions so formed protrude so as to meet, they immediately coalesce, forming a connecting chain of vessels between the buds of the scion and the roots of the stock. If an old grafted tree is cut down, and all the wood cut away to the original portions which existed at the time of grafting, it will be found that the sections made by the grafting-knife are only mechanically pressed together, and may be easily taken asunder. Instances frequently occur of the inner bark of the scion being placed out of contact with that of the stock, and a union nevertheless ensues; but this takes place in consequence of the cellular substance protruding from the respective albumums over the surface of the old wood,

which it only covers : as soon as the new-formed tissue of stock and scion touch each other, a union is then formed."

*The objects of grafting are manifold* : these, however, may be divided into three distinct heads—namely, to continue in their original purity, as well as to multiply, by extension of their parts, trees and plants which could not conveniently be otherwise increased ; to accelerate the production of fruit and flowers ; and to induce fertility.

*Grafting with a view to continue the purity of a variety of fruit or flower.*—Were we dependent entirely for a reproduction of our finest fruits and flowers upon the progeny arising from their seed, our disappointments would be great and frequent, if botanists are correct in their theory that all varieties, however improved they may be compared with the parents from which they originated, whether the intercourse between the flowers was brought about by the agency of man or from accidental causes, have a direct tendency to revert to the type from which they originated : then would all our most choice fruits and flowers revert backwards, if their propagation were continued by sowing their seeds. The quality of many seeds is liable to be affected by impregnation, occasioned by the casual introduction of the pollen of congenerous plants into the blossom ; and notwithstanding the greatest care that man can possibly take, a species of accidental intercourse is perpetually going on : so that even were plants capable, in a high-bred state, of continuing themselves in a state of purity, and of reproducing themselves undeteriorated, and supposing such a law did not exist of varieties returning, after a time, to their original type, this promiscuous intercourse would be of itself quite sufficient to warrant the adoption of propagation by extension, if the object be to maintain the improved variety. Grafting makes us independent of any such chances, as if the graft of a favourite variety or species of either a flowering shrub or fruit-bearing tree be placed on a proper stock, and the usual culture bestowed upon it, it may be continued for ages without showing signs of deterioration. Nay, even many herbaceous plants may be, thanks to M. Tschoudi of Metz, the inventor of this variety of the art, continued in the same manner. The possibility of continuing a variety beyond the natural limit of life allowed to the tree from which it was taken, was doubted by Mr Knight and some others. The majority, however, of botanists, and our highest physiological authorities, deny the truth of Knight's views, and contend that a variety may be continued by extension to an almost indefinite period. Many trees and plants may be readily multiplied by extension, that could not be otherwise increased. By this means, also, we multiply such plants as will scarcely root by cuttings or layers, and rarely produce seeds (if ever) in this country, as well as almost all other trees which contain in themselves only one sex. Willows, poplars, &c. of this class, for the most part root freely by cuttings. All our esteemed fruits are increased by extension in some of its various

modifications, as are the numerous varieties of variegated leaved, weeping or pendent-branched trees and shrubs, &c.

*Grafting with a view to accelerate the production of flowers or fruit.*—Plants originated directly from seeds are apt to grow luxuriant, and to attain both a considerable size and age before they show a disposition to produce flower-buds. This habit is corrected by removing scions of them, and working them on stocks of the same, or of some nearly allied species, by which process flowering is accelerated by impeding the descent of the properly elaborated juices of the tree, and inducing the principle of maturation instead of encouraging that of growth. The plant itself may be cut down and grafted with its own branches to produce a like effect. Grafting a young twig upon an old stock has the effect of making it flower earlier than it would otherwise do, in consequence of the accumulation of sap in the old stock becoming beneficial to the twig, and giving a check, at the same time, to its tendency to produce leaves. As an example, if a seedling apple be grafted the second year of its growth on the extremities of a full-grown tree, or even on a stock of five or six years from seed, it will show blossom-buds the second or third year ; whereas, if it had remained ungrafted, it might not have shown such buds for ten or twenty years. It is a usual practice in gardens to take shoots off seedling camellias, rhododendrons, and similar plants, and to graft them on established plants of the same species, and thus we prove their merits several years before the original plants would show symptoms of flowering.

*Grafting with a view to induce fertility.*—The laws which govern this part of the vegetable economy are almost identical with those of the preceding. Mr Knight observes, that the effects produced by grafting "are similar to those which occur when the descent of the sap is impeded by a ligature, or by the destruction of a circle of bark"—ringing, as it is practically called. "The disposition in the young trees to produce and nourish blossom-buds and fruit is increased by this apparent obstruction of the descending sap, and the fruit of such young trees ripens, I think," he says, "somewhat earlier than upon young trees of the same age, which grow upon stocks of their own species ; but the growth and vigour of the tree, and its power to nourish a succession of heavy crops, are diminished, apparently by the stagnation in the branches and stock of a portion of that sap, which in a tree growing upon its own stem, or upon a stock of its own species, would descend to nourish and promote the extension of the roots."

*Grafting with a view to renew the head.*—This is often found to be expedient, particularly in the case of old and diseased trees, and also those which have ceased to be productive. If such trees were cut down either to within a few inches of the point where they were formerly grafted, or were the larger branches amputated close to or at any distance from the main stem or trunk, abundance of young shoots would be produced, arising from innumerable

latent buds with which their bark is everywhere replete. From these, provided the stem be not cut over below the original graft, abundance of material would be provided for the future formation of the tree. But if care be not early taken to rub off all the buds as they begin to develop themselves, leaving only the proper numbers, and those well placed, the one would rob the other; and before a selection is made, the season of growth may be nearly terminated. Besides, in this case, if the tree be large, or of an indifferent variety, no change for the better takes place—only the renewal of the tree, which will be some years in coming into a bearing state. It were better, under such circumstances, to graft the tree with more choice kinds, which would not only give an improved quality of fruit, but that fruit would be produced within a much shorter space of time. The grafts could also be put on where the branches are required to be; and the sap being directed at once into proper channels, the shoots would attain a size and maturity, before autumn sets in, which would enable them to elaborate the necessary sap for the formation of fruit-buds within a very short space of time. The process of heading down and grafting old fruit-trees is a much neglected part of fruit-tree culture; and we need not point to commercial orchards only, when we see so many cases where a different course might be expected.

One of the advantages of this mode of grafting is, that the organisable matter deposited in the roots and the part of the trunk left, is thrown with great force into the scions, causing them to make strong and vigorous shoots; but as they cannot take up all this organisable matter at once, it is stored up for them in the interior of the tree, and supplied to the branches, in future years, as it is wanted: whereas, if the tree operated upon be not cut down entirely to one stem, but its branches only partially shortened, and part of them only furnished with scions, these branches will attract the juices to themselves, and greatly weaken the scions, if indeed they do not entirely perish.

*Grafting several sorts on one tree.*—In heading down old trees of large size, particularly in small gardens where only a few trees can be accommodated, this process may be advantageously adopted, and a variety procured. Even on one apple or pear tree, both early-ripening and late-keeping sorts may be produced, thus affording a long succession of fruit; whereas, if only one kind be grown, that season is greatly diminished. Many varieties of camellias may, in like manner, be produced from one plant, affording a greater variety as well as a long succession of blooms.

*Grafting to produce a reduction in size.*—This is effected by working the apple on the paradise or doucin stock, the pear on the medlar or quince; while, to produce a contrary effect, the former is grafted on the crab, and the latter on the wild-pear stock. Dwarf fruit-trees are valuable in small gardens; and indeed some nurserymen, such as Mr Rivers, have planted whole miniature orchards, the trees being much the size of ordinary gooseberry bushes.

*Choice of grafts.*—These should be chosen from the young shoots of the previous summer growth, if indeed the operation be not performed by using scions of the same season's growth, as practised by Knight, the Baron Tschudy, and others; but for general practice the outside lateral shoots are preferred, because they are less robust, and less apt to run to wood, than those from the centre or top of the tree, and not so weak as those at its base, and under the shade and drip of the rest. Besides this, they are better ripened, and are found from experience to produce the truest specimens of the fruit of the tree from which they are taken. "An exception to this rule is to be found when the trees are in a sickly state, when, of course, the grafts should be taken from the strong shoots in the centre, or near the top of the tree. The ends of each scion should be cut off, and the middle part only used, rejecting both the top and the base of the shoot. The grafts should be cut off the parent tree some time previous to their being used, experience having shown that it is necessary to allow the stock to have the advantage over the graft in forwardness of vegetation. The sap of the stock should be in active motion at the time of grafting, which would also be the case with the scion, if left on the parent tree; whereas the grafts being taken off some time before, the buds will be unavoidably kept back, and ready only to swell when placed upon the stock. Grafts should be collected any time in January or the beginning of February, and kept at their whole length, laid in dry mould, in a situation where they are not exposed to either frost or much sunshine, until they are to be used."—*Practical Gardener.*

*Choice of stocks.*—Such stocks must always be chosen as have a near affinity to the scion to be put upon them. There is, however, another reason why a judicious choice of stocks should be made—namely, that they may be adapted to the soil they are to be planted in. Hence, where the soil is damp, and subject to be overflowed occasionally with water, such as meadows by river sides, &c., the quince will be found the best stock for the pear; whereas in dry sandy soils it would be the very worst. Again, the white-beam tree is the most proper stock for the pear in chalky soils; in such soils even the pear stock would scarcely live. On properly adapting the stock to the soil, and the variety to the climate, much of the success in fruit-tree culture depends.

*The influence of the stock upon the graft.*—On this subject opinions have long been at variance, and it appears also to have attracted notice at an early period. The following may be regarded as the leading opinions offered: "Crab stocks cause apples to be firmer, to keep longer, and to have a sharper flavour. If the breaking pears be grafted on a quince stock, the fruit is rendered gritty or strong, while the melting pears are much improved on such stocks."—*Miller.* "The scion overruleth the graft quite, the stock being passive only."—*Lord Bacon.* "This, as a general proposition, remains true, it being evident that the scion, bud, or inarched shoot, is endowed with the power of drawing or forming from the stock that peculiar kind of nour-

ishment which is adapted to its nature, and that the specific character of the engrafted plant remains unchanged, although its qualities may be partially affected."—*Neill*. "The influence exercised by the stock is very marked, and it is of great importance to select good stocks on which to graft slips. In this way the fruit is often much improved by a process of *ennobling*, as it is called. The scion, also, in some cases seems to exercise a remarkable effect on the stock. Slips taken from varieties with variegated leaves, grafted on unvariegated, have caused the leaves of the latter to assume variegation; and the effect, when once established, has continued even after the slip was removed. The effects of grafting are well seen in the case of the red laburnum, when united to the yellow species. The red laburnum is a hybrid between the common yellow laburnum and *Cytisus purpureus*, or the purple laburnum. The branches below the graft produce the ordinary yellow laburnum flowers of large size; those above often exhibit the small purple laburnum flower, as well as reddish flowers, intermediate between the two in size and colour. Occasionally the same cluster has some flowers yellow and some purple."—*Balfour*. "Since, then, the developments of the graft are proved to be, in fact, altogether uninfluenced by the stock, it may be safely asserted that the latter ought to be considered as a medium only, or vehicle, through which the vascular organs of the former pass, and are conveyed into the soil, whence their spongioles and rootlets, by the aid of electric agency, affect the intro-susception of the nutritive sap. It may, however, be admitted, that in the first instance the *cellular system and juices* of the stock exert an attractive energy upon those of the graft; and that while the former affords an appropriate matrix or bed, wherein the granular excisions from the scion may affix themselves and be secured, the latter keeps up that supply of moisture which is required till the union is completely effected. A graft or scion, therefore, can be viewed in no other light than as a cutting deposited in a more congenial medium of nutrition than the soil, all the former developments of which cutting are completely its own, and wholly independent of any physical agency or influence exerted by the stock."—*Towers*. "In proportion as the scion and stock approach each other closely in constitution, the less effect is produced by the latter; and on the contrary, in proportion to the constitutional difference between the stock and the scion, is the effect of the former important. Thus when pears are grafted or budded on the wild species, apples upon crabs, plums upon plums, and peaches upon peaches or almonds, the scion is, in regard to fertility, exactly in the same state as if it had not been grafted at all; while, on the other hand, a great increase of fertility is the result of grafting pears upon quinces, peaches upon plums, apples upon white thorn, and the like. In these latter cases, the food absorbed from the earth by the root of the stock is communicated slowly and unwillingly to the scion; under no circumstance is the communication between the one and the other as free and per-

fect as if their natures had been more nearly the same: the sap is impeded in its ascent, and the proper juices are impeded in their descent; whence arises that accumulation of secretion which is sure to be attended by increased fertility. No other influence than this can be exercised by the scion upon the stock. Those who fancy that the contrary takes place—that the quince, for instance, communicates some of its austerity to the pear—can scarcely have considered the question physiologically, or they would have seen that the whole of the food commutated from the albumum of the quince to that of the pear is in nearly the same state as when it entered the roots of the former. Whatever elaboration it undergoes must necessarily take place in the foliage of the pear, where, far from the influence of the quince, secretions natural to the variety go on with no more interruption than if the quince formed no part of the system of the individual."—*G. Lindley*.

The influence of the graft upon the stock appears scarcely to extend beyond the power of communicating disease, as shown by the difficulty of inducing health and vigour in a tree that has been grafted from another in an unhealthy state, even although grafted upon a healthy stock for many times in repeated succession. Disease is certainly communicated to the stock when the infection is conveyed by scions taken from a tree in which inherent or hereditary disease exists.

In connection with the influence the stock may be supposed to have upon the graft, we may observe, that while it is perfectly possible to have a hundred sorts or more of apples upon one tree, and of pears upon another tree, each after its kind, yet no difference occurs in one of them, either in size, colour, flavour, or form, but each grows on as if it were upon a distinct stock of its own. And, again, we have white, red, and the intermediate variety of currant called the champagne by some, all growing on the same bush, and all retaining their individual characters for years. The peach, nectarine, and apricot have been wrought all on one tree, each retaining its own marks of peculiar distinction. The sap which supplies nourishment to all these is only a simple fluid collected by the roots of the stock, passing upwards through it to the fruit and to the leaves, which latter have the power of digesting and modifying it, and forming it into a proper juice, which re-descends in the inner bark; and even every bud and leaf upon the whole tree maintains its individuality, and prepares its own proper food or organising matter out of that general aliment the sap, which was conveyed, a mere simple fluid, alike to all: the leaves, therefore, have the power of preparing the food for the plant, and of conveying it to the fruit. If, therefore, any change takes place, it would be in the leaves, which are the vegetable laboratory, and not in the fruit. The sap, which ascends year after year in form of a mere simple fluid, and returns again year after year in an elaborated form, gives bulk to the branches, stem, and even to the stock; still the latter, although increased in size, is not altered in constitution, and will no more throw

out branches similar to those of the engrafted part than the latter would branches similar to those of the stock. The stock and graft remain ever distinct, although forming one and the same living subject. But while grafting or budding never effects any alteration in the identity of the variety or species of fruit, still it is not to be denied that the stock does exert certain influences over the habits of the graft. These have, however, been already noticed in a general way.

The Americans and French graft and bud their fruit trees on much taller stocks than we do, and they believe that this tends to the durability of the tree. The late Mr Wilmot was of opinion that the stock, becoming buried by the accumulation of soil in gardens, was in time transferred into a perfect root; and when this takes place the trees begin to decline in vigour, and soon after die.

*General remarks on stocks for fruit trees.*—The late Professor Thouin, who studied this matter thoroughly, observes that the historians and poets of antiquity have written, and the moderns have repeated on the faith of others, that every scion will take on any sort of stock, provided there be any resemblance in their barks! Thus Pliny, Varro, Columella, &c., speak of apples and vines grafted on elms and poplars, and of different fruits being borne on the same stock; and some of later date state even more absurd anomalies. Even to this day, if such extravagances be not really believed by many gardeners on the Continent, there are some of those who do their best to persuade us to believe that such things are; and many ingenious contrivances we have seen by which such deceptions are carried on. One of these is produced by what the French call *Graffe des Charlatans*, and is often constructed by selecting an old orange stem, with a few miserable branches on top, into which they drill holes from the bottom of the stump upwards, through which they ingeniously introduce slender shoots of roses, jasmines, and like flexible plants, the roots being planted in the same soil as the orange, the shoots being introduced below the surface of the soil, and the points of the tops brought out at various heights of the orange stem.

The classical reader will no doubt recollect Pliny's account of the tree in the garden of Lucullus, grafted in such a manner as to bear apples, pears, plums, almonds, olives, figs, and grapes. Similar ingenious deceptions are practised in Italy to this day.

Mr Rivers, a highly respectable nurseryman, has long paid great attention to the subject of stocks, as well as several others, who have given us the benefit of their experience in various forms. One of the most experienced writers on fruit trees—Mr Errington—in a valuable article in the "Journal of the Horticultural Society," after remarking that other causes must be at work, beyond the mere question of a deficiency of heat in our climate, to prevent the finest Flemish pears arriving at full maturity, observes, "If the habit of the quince was duly considered, and the soil adapted accordingly, the result would be a much higher amount of success than is at present attained. I do not wish it here to

be inferred," he says, "that I would advocate the total banishment of the pear stock from our gardens; not by any means. What I would urge is, that most of the Flemish kinds which are not found to succeed in a satisfactory way on the wall, would probably be much improved if grown as dwarf standards or pyramidal trees, providing proper means are taken to subdue, and continue under control, their tendency to produce superfluous shoots. The production of such shoots constitutes the principal reason why the fruit becomes unsatisfactory. The tree is in exciting soil, perhaps, with unlimited power to range in quest of food; the necessary consequence is, that abundance of breastwood is formed. Now, it so happens that the amount of foliage on such breastwood is not an iota more than is requisite to elaborate the great amount of watery juices thrown into the system. No: nature, true to her principles, produces no more foliage than is necessary for a due amount of reciprocation between the root and the branches. The tree is half stripped of its elaborative powers at the moment they are most needed, and the consequence is large fruit filled with half-elaborated juices. The gardener, to be sure, is obliged to cut away the breastwood, or general barrenness would be the result." This refers to the practice of what is called summer pruning. If a proper dwarfing system, Mr Errington believes, were adopted, there would be little occasion for disbudding. "There are three ways," he observes, "of arriving at this end: the one by using the quince stock; the next, by the free stock in a limited amount of soil; and a third, by root-pruning. The free stock, with a very limited amount of soil, offers a chance of striking at the root of the evil. If, however, the limitation is very severe, and the soil too light, there arises another source of failure; the fruit, in a hot dry summer, may become stunted, and crack. To be sure, top-dressings will obviate these things, but it would be preferable so to establish pear-trees as that they would require little or no assistance in the way of labour. We come now to the quince stock; and to this I would beg to draw particular attention. I think there can be no doubt of the general success of the quince, provided those who adopt it could be prevailed upon to prepare the stations for its reception with some regard to the habits of the quince. It will be at once admitted that the great object here is to provide a congenial soil for the stock; this done, the success of the graft will follow as a matter of course." With a view to modify the luxuriance of the free stock, this high authority suggests a system of root-pruning, to commence even while the stocks are in the seed-bed, by means of frequent transplanting, to check the tendency in them of forming strong and forked roots, and to induce them to form plenty of fibrous roots near the surface. By this means, and placing the roots afterwards under proper control, it is probable that the pear upon free stocks may come to assume a dwarfish habit—and if so, it would be desirable, as any ordinary garden soil would suit it; whereas, if the quince is used, a soil and other conditions must be artificially prepared for it. Some pears succeed bet-

ter on the quince stock than others, but all are similarly affected in assuming a diminished habit, and most of them an increase in fertility.

*Pear stocks* are obtained by sowing the seeds of the cultivated pear, and are, to distinguish them from those produced by sowing the seeds of the wild pear, called free pear stocks, while the others are called wild pear stocks. They are both more hardy and more durable, and hence adapted for standard trees in the formation of orchards. On the Continent great attention is paid to the different kinds of stocks, which nurserymen form into three classes to suit intending purchasers. The quince stock is propagated from layers, which no doubt adds to its property of dwarfing the trees for which it is used.

Most cultivators bud such pears as are intended for standards or for walls, and graft those intended to be grown as dwarfs, as in the latter case the tree divides into branches the first year, and is at the end of that period almost as far advanced in its formation as a budded tree will be at the end of the second year.

*Apple stocks*.—The stocks employed for the apple are the wild crab, which is procured by sowing the seeds of the most healthy wildings found in the woods. It is the most durable, and least subject to canker. The free stock is the produce of seeds of the cultivated apple, and ranks next to the former in durability and hardihood. The doucin, or paradise stock, is preferred for dwarf standard trees and espaliers. It is less durable than the crab stock, is reared by layers, and succeeds better in a rather rich moist soil than in a poor dry one. The French stock is also reared by laying, and is the most diminutive of all stocks—used principally for trees to be grown in pots, or planted as miniature orchards. Budding is preferred for apples intended for full standards, the bud being inserted within 9 inches of the ground; while those intended for dwarfs, espaliers, and most of the delicate-growing sorts, are grafted for reasons already given.

The Paradise stock, like the quince, has the natural property of emitting numerous fibrous roots near the surface of the ground, and also of controlling the vigour of the graft, and inducing an earlier state of bearing in the tree. There are three varieties of Paradise stocks used on the Continent—viz., the Doucin, Pomme de Paradise, and the Pomme de St Jean. The two former are used for different purposes—the first for dwarf trees, and the second for pyramidal ones. It is, however, rather too delicate for our climate, unless in the most favoured situations, though of all others the best for trees to be grown in pots. The Pomme de St Jean is of a hardier character than the true Paradise, although not quite so dwarf. The Doucin is much more vigorous, and, with the English Paradise stock, the most worthy of our attention for the production of fruitful pyramids.

*Apricot stocks*.—The stocks usually employed for this purpose are, the common plum, the muscle plum, the pear plum, the common apricot, and the Brussels or St Julian stock, which latter is preferred for standard or rider trees. The first of these is obtained by sowing the stones of that plum, and is regarded as one of

the best for the purpose, and hence very extensively employed; the second from seeds of the pear plum, so called from the shape of the fruit; the third from stones of any of the cultivated sorts, but it is considered inferior to stocks from various species of plums; the last has been long used in this country, and is well adapted for the apricot, but not for peaches, being too full of sap at the budding season. The late Mr Knight anticipates that, by budding the Moorpark apricot upon the apricot stock, it would become hardier, and less subject to that disease or state of debility which is supposed to be the cause of its branches dying off during summer. Rogers, who is an excellent practical authority, says there are two stocks the Moorpark may be wrought on—viz., the muscle for dwarf trees, and the Brussels for riders and standards.

*Plum stocks*.—The plum is wrought upon the Brussels stock and common plum stock, and apparently with equal advantage.

*Peach and nectarine stocks*.—“These are usually propagated by budding only, and the stocks used are either the Brompton stock, muscle plum, or pear plum. The latter is the best, and therefore used for French peaches and others of our finer sorts. It is said that peaches wrought upon the pear plum stock are much less liable to mildew than those upon the common muscle stock; the muscle is the best for English peaches. The Brompton stock is strongly disapproved of by Mr G. Lindley, who says: ‘Where trees of a permanent character are required, the substitution of such a stock cannot be too strongly condemned.’ On the other hand, Rogers—by no means a slight authority—as well as the most eminent nurserymen, are of a different opinion. It may have happened that a dislike to the Brompton stock arose from seeing the fate of apricots budded upon it, for which fruit it is ill adapted and unsuitable. The late Mr Ronalds says: ‘I have no reason to think that the Brompton stock will not bear as fine fruit, and last as long, as either the muscle or pear plum, if budded low for dwarfs.’”

*Quince stocks*.—The quince is generally propagated by layers, where the object is to procure them for stocks for pears. If laid during winter, the plants will be rooted by the following autumn, when they should be transplanted into nursery lines, when in two years they will be fit for grafting. They are also propagated by cuttings, put in during winter; and the better varieties, intended to be cultivated for their fruit, are grafted, the stem being trained to a clean rod to the height of 4 or 5 feet.

*Almond stocks*.—The plum stock is preferred for cold and wet soils to those of the peach or the almond itself, being much harder than they. The peach stock is thought by Mr R. Thomson to be less durable than the almond, and more apt to die off in this case, as they are apt to do when used as a stock for the peach and nectarine. Almond stocks are procured by sowing the seeds when the object is to grow them for stocks, as well as for obtaining new varieties.

*Cherry stocks*.—The small black or wild red cherry of our woods is generally chosen for this purpose. The Morello cherry has been recom-

mended with a view to render the trees of a dwarf habit; and the Mahalab cherry has been suggested for a similar purpose. These are all obtained by sowing their seeds, which, if sown in spring, will come up the same season, and should not be transplanted till the second season after sowing. They will be in fit condition to bud the season following, if intended for dwarfs, but not until the second, third, or even fourth year, if intended for standards; though as regards this much depends on the strength they attain. Standards should be budded or grafted 6 feet from the ground—the former process being performed during summer and the latter in spring, and also in all cases where budding may have failed. The cherry does not succeed equally well in all soils, and we believe that much of this depends on the kind of stock employed. The wild cherry stock is best adapted for strong damp or clayey soils, and the Mahalab for soils of a light sandy or chalky nature. Stocks originated by sowing the stones of the cultivated varieties are of short duration, and subject to gum, and shed their blossoms without setting their fruit; on these accounts, therefore, they should never be employed.

*Medlar stocks.*—The Whitetorn stock has been, but very improperly, used as a stock for this fruit. The common pear stock is the most natural, and therefore the most proper, for the purpose of either budding or grafting.

*Rose stocks.*—The rose is propagated by budding, from cuttings, layers, suckers, and seeds. The more valuable varieties are increased by the former method, as, if the operation be properly performed, every bud will form a distinct plant. Budding is also had recourse to in the formation of standard roses—a taste of Dutch origin, imported into France, and from thence, in 1803, brought into England. The stocks in general use have been the tree rose, *Rosa villosa*, *R. canina*, *R. rubiginosa*, *R. tormentosa*, *R. pomifera*, &c. These have been collected from the woods in a wild state, planted in nurseries, and budded the same year or the following spring. Notwithstanding the great demand for rose stocks annually, little has been done by cultivators to improve or render more certain the supply. Of late the *Manettii*, crimson Bour-sault, and some other strong-growing kinds, have been employed; and for perennials, Bourbons, Noisette, Chinas, Teas, &c., the *Manettii* stock is recommended. But budding must be performed in September; if earlier, the buds are apt to perish in consequence of the watery nature of the stocks. July and August is the proper time to bud, when the dog rose is used as a stock.

*Stocks in general, physiologically and anatomically considered.*—There are certain relationships existing between plants, beyond which it would be impossible to produce a union by the process of grafting or budding—somewhat analogous to that limitation which prevents cross fecundation from taking place in the flowers of plants of dissimilar species. Neither process would be successful by employing plants of such remote relationship as the melon and the vine, the potato and the cabbage, &c. These limits, so far as grafting or budding is concerned, de-

pend anatomically on the organic structure of the tissue, and physiologically on the vital functions of the plant. The anatomy of plants is yet so little known, even to botanists, as well as to general cultivators, that they are unable to determine by dissection the plants which bear sufficient analogy to each other to cause them to produce either of those unions to which we have referred, and therefore all we at present know of the matter is what is taught us by practical experience. "From this it is found that as plants of the same natural family have an analogous organisation, they alone can be grafted on one another with any prospect of success; though the success of the operation, even within this limit, will not always be complete, partly perhaps from some difference in organic structure, as in the case of the apple and pear, which can only be united for a few years, but chiefly on account of the physiological differences which may and do frequently exist. Decandolle succeeded in grafting the lilac and the fringe tree on the ash, the fringe tree on the lilac, and the lilac on the phillyrea, and the olive on the ash and the privet; and although these grafts did not live a long time, on account of the physiological differences of the species, yet their having succeeded at all sufficiently proves the anatomical analogy of plants within the same natural order. This analogy is greater between plants of the same genus; more so still between individuals of the same species; and most so between branches of the same individual."—*Sub. Hort.*

Dr Van Mons considers grafting upon small pieces of the roots taken out of the ground, and planting the same as soon as grafted, to be of all others the best mode with regard to the condition of the grafted sort—*first*, because the smallest quantity of the stock is used; and, *second*, because the lower part of the scion being thus placed in the ground, after a time it throws out fibres from that portion, and so at last is actually growing on its own roots.

There are other conditions in which a union by grafting cannot take place—*viz.*, plants with milky sap, as most species of *Euphorbia*, will not unite with those having thin, watery juices. Thus *Acer platanoides*, for example, being the only species of that genus having milky juice, cannot be grafted on any others of that family. Any two plants whose sap is not in motion at the same period, cannot be successfully grafted. Although in the case of the common laurel and cherry an adhesion takes place, their union cannot be calculated upon beyond three or four years. Soft-wooded trees or plants will not readily associate with hard-wooded ones; nor woody plants with such as are herbaceous; nor will annuals with perennials.

*Season of grafting.*—The number of plants upon which this operation is performed is so great, and their constitutions and circumstances so variable, that no definite period can be fixed upon as a general rule. From what has been said of the phenomena of the art, it will have been understood that the period of operation is to be entirely guided by the state of the ascent of the sap. The spring, therefore, is the proper

season for apples, pears, and all similar hardy trees, in our climate. There is, however, an exception to this otherwise very general rule practised both in Germany and in North America, where, the stocks having been taken up in autumn, are kept in sheds or cellars, and grafted during the winter. The whole stock of a nursery may thus be done when no other work could be carried on out of doors; and when spring returns, the stocks, with their grafts tied and clayed in the usual manner, are taken out and planted. The same practice is often followed in Britain in the case of roses and pears, particularly in the latter case, when root-grafting is employed. The vine is best grafted when in leaf; if done sooner, it is apt to bleed to the extent of preventing the union from taking place. The general rule, however, is, to let the sap in the stock be in full motion, while the sap in the scion is only beginning to flow at the time of operating. "This mode of reasoning," says Mr Towers, "appears to be founded upon the old theory of the exclusive agency of the ascending sap; and it implies that the scion is in a dry and thirsty condition, eager to imbibe the ascending fluid. The electrical theory considers the flow of the sap as an operation of induction—that the buds of the twigs are the immediate instruments by which that induction operates—and therefore, that just in proportion to the identity of condition subsisting between the scion and the stock, will be the speed and certainty with which the union between the two is effected. What experience may finally determine," says this authority, "I know not; but I am prepared to say, that I have instances now before me—all of successful grafting—wherein the scions taken off the tree at the moment of 'grafting in the crown,' were more speedily knitted to the stock than others that had been cut off and kept in mould for some weeks before they were wanted."

Rhododendrons and azaleas, and most similar plants, succeed by grafting in March, using scions of last season's growth; or they may with equal success be wrought in autumn, using scions of the same year's growth. Plants growing in hot-houses, and subject to artificial excitement, may be grafted at almost any season, if the wood be in proper condition.

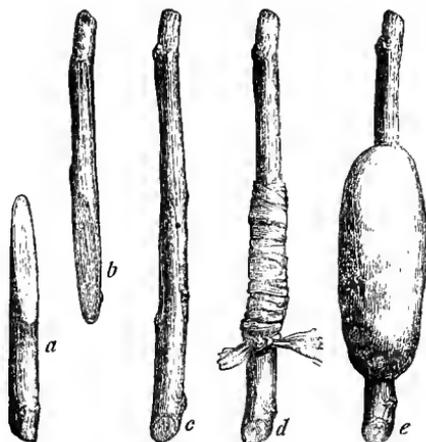

Hard-wooded deciduous trees, such as the oak, elm, &c., should be grafted in April, cutting the stocks down to within 6 inches of the ground, using scions of the previous year's growth, and, when clayed over, earthing up all round.

Succulent plants, such as Cacti, &c., should be grafted in August; they succeed best when the scion is cut in form of a wedge, and inserted in the crown or along the angular sides of the stock: no claying is necessary, only a little soft moss or cottony matter wound round the part of union to prevent the entrance of moisture. Partial shade is necessary until the union has taken place.

The operation of grafting will be readily understood by a glance at fig. 99, *a* being the stock, and *b* the graft or scion; as will be seen, a smooth sloping cut is made in an upward direction on the stock, while a similar cut is made

in the scion, but, of course, in an opposite or downward direction. These two cuts are

Fig. 99.

SPLICE-GRAFTING.

made so that the inner bark of the one corresponds with the inner bark of the other; they are then placed together (*c*), and secured by matting (*d*), to keep them in their places, and covered with clay or other adhesive matter (*e*), to exclude air, &c. The operation is most simple when both stock and scion are of exactly the same size; when otherwise, the operation must be varied to suit the circumstances: the chief point, however, is so to shape the incisions that the inner bark of the one may fit the inner bark of the other; and the more these are brought into immediate contact together, the greater certainty attends the operation.

*Whip, splice, or tongue grafting*, fig. 100.—This is the mode adopted by most nurserymen, as being the most expeditious and certain when applied to young trees, whose stocks are not much more in diameter than the scion. In performing the operation, the stock (*a*) is cut over at the height the graft is to be put on; then, with a very sharp thin-bladed knife, cut a thin slip of wood and bark upwards, about 3 inches below the top of where the stock has been cut over. In making this cut, insert the edge of the knife rather horizontally; and when it has gone through the bark and nearly to the middle of the stock, pull the knife straight upwards, making the cut with one pull. Then, about half way down this cut, cut a thin tongue not more than three-eighths of an inch in length. In the same way proceed with the bottom part of the scion, *b*,

Fig. 100.

WHIP OR TONGUE GRAFTING.

ing the most expeditious and certain when applied to young trees, whose stocks are not much more in diameter than the scion. In performing the operation, the stock (*a*) is cut over at the height the graft is to be put on; then, with a very sharp thin-bladed knife, cut a thin slip of wood and bark upwards, about 3 inches below the top of where the stock has been cut over. In making this cut, insert the edge of the knife rather horizontally; and when it has gone through the bark and nearly to the middle of the stock, pull the knife straight upwards, making the cut with one pull. Then, about half way down this cut, cut a thin tongue not more than three-eighths of an inch in length. In the same way proceed with the bottom part of the scion, *b*,

making a sloping cut of about the same length as the cut in the stock; then make a tongue to correspond with that in the stock, but cut upward instead of downward. The scion is then to be placed on the stock, inserting the tongue of the former into the tongue of the latter (c); bring the two edges of the cut in the top of the stock and the two edges of the cut in bottom of the scion to meet exactly; or, if the graft be larger than the stock, so that both edges of the bark of the former cannot meet the corresponding edges of the latter, then let one of the edges meet—but this must be done with great precision. The stock and scion, being thus joined, must be bound closely together by soft matting, beginning to wind it round the stock an inch or two below the part grafted, and continued upward to the top of the stock; and this, if well done, will in many cases be sufficient to secure success even without the application of clay. A ball of well-prepared clay (some use grafting-wax) is then formed round the stock and scion, when the operation may be considered finished. The use of the clay or wax is in order more effectually to exclude the air until the union takes place; and both this, and the chance of the clay falling off during dry weather, will be secured by drawing up earth around the ball so as nearly to reach its top—that is to say, when the graft is put on near the ground. When it is placed at a greater height, such as in the case of standard trees, then a little moss or soft hay tied over it will be equally efficient as a non-conductor of heat and moisture. The clay or wax envelop is intended also to preserve the graft in a uniform temperature, and so prevent the rising sap from being checked by cold days or nights. When the scion and stock are both of kinds that do not unite freely, the tongue is sometimes omitted, but in that case more care is required in tying. In the case of shoots having much pith, such as those of the rose, the graft is often put on the stock without being tongued into it.

In the French mode of whip-grafting there is no more pared off the stock than exactly the breadth of the scion; and in the early days of grafting in this country it was performed without a tongue, the addition of which gave rise to the term, as that of whip-grafting owes its name to the manner in which the scion and stock are cut so as to fit each other when secured in the manner of a whip-thong to the shaft or handle. The term splice is borrowed, evidently, from nautical phraseology.

Sometimes, in this mode of grafting, the stock is not shortened down to the scion, but a portion of it is left with a bud at its extremity, the better to secure the rising of the sap to the graft. Some operators cut a notch in the scion immediately under a bud, which notch is made to rest on the top of the stock; and if both stock and scion are of the same size, the top of the latter is certain of being healed over the first season.

A sub-variety of splice-grafting, fig. 101, is often practised in the case of peaches, "nectarines, apricots, and other tender shoots with large pith. It is found of advantage to have a

quarter of an inch of two-year-old wood at the lower extremity of the scion, and to have the stock cut with a dovetail notch.

Fig. 101.

SPLICE-GRAFTING  
THE PEACH.

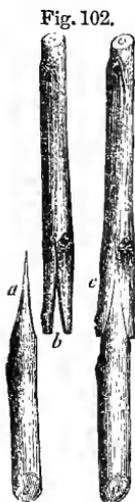

In the case of the fruit trees mentioned, the buds of the scion on the back and front are removed, leaving two on each side and a leader; and when these have grown 6 or 8 inches, their extremities are pinched off with the finger and thumb, by which means each shoot will throw out two others: this produces in autumn a finely-shaped tree with ten branches. Such trees will bear two or three fruits the second year from the graft."—*Gardeners' Magazine*.

Downing describes American whip or tongue grafting as follows: Having chosen the stock, "cut it off at the point where it appears best to fix the graft. If the stock is quite small, it may be within 3 or 4 inches of the ground. Then, with a very sharp knife, make a smooth cut upwards about 2 inches in length.

Next make a slit from the top of this cut about one-fourth of the way downwards, taking out a thin tongue of wood. Cut the scion 4 or 5 inches long, or so as to have three buds; then shape the lower end with a single smooth sloping cut about the same length as that on the stock, and make the tongue upward to fit in the downward slit of the stock. Now apply the scion accurately to the stock, making the *inner bark of the scion fit exactly the inner bark of the stock, at least on one side*. Without changing their position, tie them together carefully with a piece of best matting or tape, and finally cover the wound with well-prepared grafting clay or wax. This ball of clay should more than cover the union by an inch above and below, and should be about an inch thick. If grafting-wax be used, it need not be above half an inch thick. About the middle of July," for plants in the open air, "after a rainy day, remove the ball of clay, and if the graft is securely united, also the bandage; and the angle left at the top of the stock should now be cut off smoothly, in order to allow the bark of the stock and the scion to heal nearly over the whole wound." Mr Downing further remarks, "Though it is little attended to in common practice, the amateur will be glad to know that the success of a graft is always greatly insured by choosing the parts so that a bud is left near the top of the stock, and another near the bottom of the scion. These buds attract the rising sap to the portions where they are placed from woody matter, and greatly facilitate the union of the parts near them, the upper part of the stock and the lower part of the scion being the portions soonest liable to perish from a want of nourishment."

*Saddle-grafting* (fig. 102) is practised only where the stock is of moderate dimensions. The stock (a) is cut into a wedge-like form, and

the scion (*b*) slit up the middle so as to adapt it that it shall be seated across or ride upon the former (*c*). This mode was invented by Mr Knight, and used by him chiefly upon cherry trees; and he states that even where the wood has been so succulent and imperfectly ripened as to preclude every hope of success by any other mode, he found this most successful.

SADDLE-GRAFTING.

The advantage of this mode consists in offering the largest surface for the junction of the scion and stock, but, as in whip-grafting, the bark must, at least on one side, be neatly fitted to the bark on the other. Fig. 102 will show the principle.

A variety of saddle-grafting is much used in the Herefordshire orchards, of which fig. 103 is a representation. In this case the scion must be much smaller than the stock, and is split up between 2 and 3 inches from its lower end, so as to have one side stronger than the other. This strongest side is introduced between the bark and wood, while the thinner division is fitted to the opposite side of the stock. Mr Knight, who described this mode in the "Horticultural Society's Transactions," says that the apple and pear grafted in this manner seldom fail, and that it may be practised with success either in spring upon last year's scions, or in July with the young wood of the current year. He attributes one advantage to saddle-grafting which must appear very clear—namely, that the sap is not driven from its natural course, but ascends from the stock to the scion freely, which is not the case when the scion is put on one side of the stock only, as in almost all other methods.

HEREFORDSHIRE SADDLE-GRAFTING.

*Cleft-grafting* appears to have been one of, if not the most primitive of all modes, which may be naturally inferred from its great simplicity. Although easily performed, it has a clumsy appearance, but is yet very useful in the case of old trees requiring to be cut down from old age, disease, or other causes. Fig. 104 will show the principle. *a*, the stock, of almost any diameter. Two grafts (*b c*) are here shown, but there may be several, according to the size of the stock. The operation is first sawn over, and afterwards smoothed with a knife. A cleft is then made in the stock with a hammer and splitting knife, or as often with a carpenter's chisel. The scion

into the cleft as the knife or chisel is withdrawn, taking care that the inner bark of the scion fits to that of the inner bark of the stock. When the number of grafts desired is inserted the whole is bound round with matting, and clayed in the usual manner.

CLEFT-GRAFTING.

"Apple stocks in many American nurseries," according to Downing, "are grafted in great quantities in this mode, the stocks being previously taken out of the ground, headed down very near the root, cleft-grafted with a single scion, sloping off with an oblique cut the side of the stock opposite that where the graft is placed, and then planted at once into rows, so as to allow only a couple of buds of the scion to appear above ground. It is not usual with many either to tie or clay the grafts in this case, as the wound is placed below the surface; but when this plan is adopted, the grafts must be set and the trees planted at once, drawing the well-pulverised soil with great care around the graft. Another way of grafting apple stocks common in some western nurseries consists in tongue-grafting on seedling stocks of very small size, cut back almost to the root. This is performed in winter by the fireside!—the grafts carefully tied, and the roots placed in the cellar in sand till spring, when they are planted, the top of the graft just above the ground."—*Fruits and Fruit Trees of America*. Cleft-grafting with one scion is in general not a good mode, because if the split has been made right through the stock, it is in danger of being injured by the weather before it is covered by wood by the scion. If the cleft is made only on one side of the stock, the evil is mitigated; another objection arises when only one scion is used—the tree becomes, as a matter of course, attached, as it were, to one side of the root only.

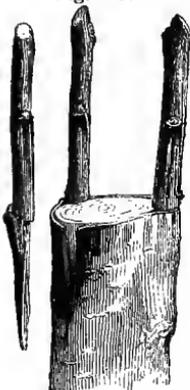

*Cleft-grafting the vine*.—This is sometimes done, and in the following manner: A spur is cleft, commencing the incision exactly above the second eye; the scion, when chosen, is cut in a wedge-shape form at its base, commencing the slope of the wedge immediately below a bud, so that when the scion is inserted into the cleft, the bud of the latter and that of the stock may be placed opposite each other, which is considered the most favourable position for success. The process of tying and claying goes on in the usual manner, with this exception, that a small hole is left in the clay opposite to the bud of the scion, to allow that bud to develop itself freely. When the scion has grown fourteen or fifteen days, it is then headed back to one bud, which is left to draw up the sap until the union has fairly taken place between the stock and scion. The proper season for grafting the vine in this way is when the shoots have made four or five leaves; if done sooner, there is a danger of the sap flowing so fast as to prevent a union taking place by what is called bleeding.

This process is often adopted in grafting suc-

culent plants; and some Continental growers employ it in the propagation of roses and camellias. For the latter purpose it is of considerable importance, as each individual bud is made to form a plant, the scion being cut so that only one bud is attached to each.

*Crown-grafting* is merely a variety of cleft-grafting, and is sometimes called rind-grafting. It is practised upon old trees, either for their total renewal, or upon large amputated branches, to renew by degrees. It is, upon the whole, a better mode than cleft-grafting, because the stock, if old, is

Fig. 105.

CROWN-GRAFTING.

not subjected to the chance of being split, the scions in this case being placed between the bark and the wood. Fig. 105 will illustrate the process. It is performed later in the season than cleft-grafting—that is, from the end of March to the end of April—because then the bark separates more freely from the wood than at an earlier period. In rind or crown grafting, great care must be taken that the bark of the stock be not bruised during the process of opening the bark for the reception of the scion, and for this purpose a proper spatula or grafting-knife should be used. Some use a piece of hard wood, fashioned in form of a scion, and others one of bone or ivory; the use of these is to separate the bark from the wood without injuring the former. The scion is prepared without a tongue, and is placed in the stock so that its wood may be in contact with the alburnum of the stock. Sometimes it is cut with a sort of shoulder at the top of the cut, that the graft may rest on the wood of the stock, and in this case it is called shoulder-grafting.

Fig. 106.

PEG-GRAFTING.

The graft being prepared in either way, the bark of the stock is opened to the extent of 2 inches, and the scion is made to pass down between the wood and the bark. If the bark of the stock is hard and dry, and does not yield readily, it may be scored or cut perpendicularly downward, to enable the operator to open it, so that he may thrust the scion into its place with its cut side next to the wood: this being done, tying and claying is followed as in former cases.

*Peg-grafting.*—This is one of the oldest varieties of this mode of propagation, although now seldom used. The annexed cut, fig. 106, and a brief description, will sufficiently explain its principles. The stock is cut over horizontally at the desired height, and a hole is drilled in the centre to

receive the end of the scion, and this hole must be in proportion to the size of the tree to be operated upon: if for a small tree (for it should be understood that the scion in this case may comprise the whole tree) or plant, a  $\frac{1}{4}$ -inch gimlet will be sufficient; but for one of large dimensions and spreading head an augur of 2 or 3 inches may be used. The depth to which this perforation should be made will, for obvious reasons, be determined by the size of the scion. The scion should also be of the same diameter with the stock, and so fashioned that a portion of its lower end is reduced, leaving only so much of the centre as will form a peg (from thence the name) or dowel, in the phraseology of carpenters, to fit exactly into the perforation, so that, when the surface of the section of the stock and scion come together, the bark and alburnum of each shall be exactly opposite to each other, which leads at once to the conclusion that the diameter of both stock and scion should be equal. When the scion is thus fitted on top of the stock, the graft or top of the tree is supported firmly in its upright position by props, to secure it against displacement by winds, &c. The place of junction is carefully clayed round; and if the operation is performed close to the ground (which, although not in all cases necessary, is in most instances expedient), is covered over with soil, the better to exclude the air. By this means trees of almost any size may be grafted, so long as we have mechanical power to elevate them, and keep them in their proper place. This was accomplished prior to 1817 by Dr Van Mons of Brussels, who inserted an entire tree on the stump of another. This rather uncommon effort in the art of grafting was shown to the late Dr Neill in 1817, who describes it as follows in "The Horticultural Tour," p. 310: "A neighbour having, in the spring season, cut down an apple-tree about 15 feet high, which Dr Van Mons considered as a desirable kind, and a good healthy tree, he immediately selected a stock of similar dimensions, and, cutting it over near the ground, placed on it, by the mode of peg-grafting, the foster tree, supporting the tree by stakes, and excluding the air as we have noticed above." The experiment succeeded perfectly, the tree becoming, in course of the second summer, nearly as vigorous as ever.

Figs. 107, 108.

FRENCH AND ENGLISH

SHOULDER-GRAFTING.

The same tree we saw in 1832, in as vigorous a state of health as any in the garden.

*Whip-grafting in the French manner.*—The French propagators never pare more off the stock, whatever its size may be, than exactly the width of the scion.

*Shoulder or chink grafting* will readily be understood by the annexed figs. 107, 108. It is best adapted for trees or

branches of which the stock and graft are of the same diameter.

*Side-grafting* is merely a modification of whip or splice grafting, and is performed on a stock whose head is not cut off, or on a branch without its being shortened. The great utility of this mode is the facility it offers of supplying branches to parts of trees where they may have become too thin, or making a branch in case of accidents. It is usefully employed upon wall or espalier trees that have become naked of fruit-buds towards the centre, while they may have abundance towards their extremities. Branches of the same kind, or of other kinds if desired, may be by this mode put on at the base of the old branches, and the young shoots trained over them as they advance, thus providing young and bud-producing wood at those parts of the trees which must have otherwise remained in a state of sterility. The same may be done upon standard fruit-trees with a like effect, and ornamental trees and shrubs may be again clothed with young wood at those parts where, from mismanagement or otherwise, they may have become naked. There is only one disadvantage attending this mode, which is, as the branches on which the operation is performed have not been cut back, the scions are less likely to take: as the flow of the sap is not materially interrupted, it is apt to pass without forming the union between the graft and the branch. This may, however, be so far remedied by bending down the branch to as low an angle as possible, which will tend to moderate the rapidity of the sap's flow; or a tight ligature may be placed on the branch a little above the graft. The French have a variety of side-grafting, which they call veneer-grafting, and which they employ in working young oranges and camellias. For this purpose they form the incision in the stock by taking a very thin slice out of it, and leaving a sort of shoulder at the lower extremity, upon which the scion is made to rest. This is one of the neatest modes in use, as, if well done, the union becomes so complete as scarcely to be detected afterwards. Another variety of side-grafting is practised on the vine in its dormant state. An opening is cut out of the branch to be operated upon from 2 to 3 inches in length, and to the depth of about half the diameter of the branch, the ends being cut obliquely, something in the dovetail form. The scion is cut so as to fit this space, tied round, but not clayed, as the branches should be laid down so that the grafted parts may be covered with moist soil. About a month thereafter the plants are plunged in a mild bottom-heat, and in about the same length of time the young shoots will begin to show themselves. Wedge-grafting is also a modification of side-grafting, and is advantageously employed in the propagation of the *Deodora* and other *Ceniferæ*. We believe this method owes its origin to Mr Barron, who describes his plan in "The Gardeners' Magazine," and from which we learn that both the scions and stocks are of the wood of the preceding season's growth; that the slit in the stock is cut through the pith, and is from 1 to 1½ inches in length. The scions used are from 3 to 5 inches long; they are inserted in the

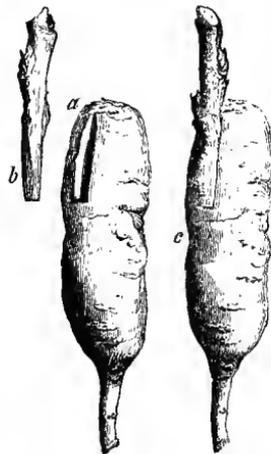

usual manner, and grafting-wax is used instead of clay, as being lighter, and therefore less liable to bend down the heads of the stocks.

*Root-grafting*.—This method is often practised in nurseries, in cases where stocks of the species intended to be increased are scarce; and at other times, as in America and Germany, as has been already noticed, to economise time, as the operation can be performed during winter and under protection, so that, when spring arrives, they may be taken out and planted in nursery lines. One precaution ought to be taken in this mode—namely, washing the top parts, at least of the root stocks, to prevent the possibility of earthy matter getting between the scion and stock. The mode of attachment may be any of those already described, as the whole difference consists in forming a union between a scion and a root instead of a stem. When the attachment has taken place, and planting is completed, draw up the earth around the neck of the plants so as to cover the point of union. The rarer species of oaks, for example, may be grafted upon the roots of the common sorts; and the otherwise useless roots left on the ground, upon removing old thorn hedges, may be used as excellent stocks upon which to attach pear-grafts.

*Herbaceous grafting*.—This is comparatively a modern invention, discovered by Baron de Tschudy, and consists in attaching the solid parts of herbaceous plants, or of woody plants when in an herbaceous state, to others of the same or sufficiently nearly allied species, while in a similar state. The tree Peony has been successfully grafted upon the fleshy roots of the herbaceous kinds of the same genus; the melon and cucumber, the potato and love-apple, have been frequently grafted upon each other; and almost the whole of the cultivated *Brassicæ* have been or are capable of being grafted on each other. These latter are, however, to be regarded more in the light of experiments than of useful adaptations.

In the case of the tree Peony, fig. 109, the operation is performed from the middle of July to the middle of August. The tubers throw out roots in autumn, and are then taken up and potted, and preserved under cover during winter. The operation is exceedingly simple, and consists in selecting single tubers of the plant, in which a triangular notch, *a*, is cut near its top; to this notch a scion of the tree sort, *b*, is made to fit, having two or three buds upon

Fig. 109.

ROOT-GRAFTING THE TREE PEONY.

it; when placed, *c*, it is tied with soft matting, and clayed or waxed over in the usual manner. If the plant which supplies the scions be scarce, then one bud may be used instead of three. In selecting the tubers for this purpose, barren ones—that is, those having no visible eyes—are as good, if not possibly better, than those which have them. By this means dahlias may be multiplied largely, as every tuber is suitable for a stock, while only the crown of the whole root produces cuttings.

*Grafting annual and perennial plants* is possible; we have yet, however, we confess, to learn its utility.

*Expeditions grafting.*—In nurseries and large plant establishments every means to secure stock of a new or rare plant is of vast importance; and hence many ways have been tried to effect this end. Heat, moisture, shade, and slow excitement are the necessary conditions, and hence the operation is going on at all seasons, and the success attending it, in judicious hands, is truly astonishing. For as soon as a new plant is procured, an almost certain calculation is made according to the number of leaves or buds on it, that in a few weeks as many plants will be produced as there are leaves or buds on the original. The French adopt a very appropriate name for this species of propagation; they designate it *Grefte étouffée*, or stifled graft, from the process being carried on under closely-covered bell-glasses to exclude the air. The plants, being small, are in pots plunged in bottom heat, and in this state they are kept until a union takes place. Almost every first-rate propagator has his own way of putting on his grafts, or rather buds; for, as we have said, every bud is made available, and expected to produce a perfect plant. The cleft form is often adopted, but almost any of the others, under judicious modifications, are equally applicable. Great care is, however, taken that the scion or bud be placed on the stock near to a bud, and this bud must be scrupulously preserved, as on that much of the success depends. When the bud or scion is placed on the stock, it is secured with a soft worsted, cotton, or other thread, and the place of union, as well as the top of the stock not covered with the scion, is covered with a thin coating of grafting-wax. Sometimes, however, a little moistened cotton or fine moss is used as a substitute. As the moisture arising under the bell-glass would soon become too great for the plant in its yet tender state, that covering is frequently removed, and wiped clear of the condensed steam; air is admitted, after the first three or four days, by little and little at a time, until the union has taken place, when it is more abundantly supplied, and ultimately the glass is removed altogether. The principal thing required in this delicate operation is neatness in execution, and rigid attention to the conditions we have named above.

*Grafting Conifera.*—Somewhere about 30 years ago, the Baron Tschudy practised the grafting of the *Pinus laricio* on the common Scotch fir in the forest of Fontainebleau; a description of his method has been published in "The Gardeners' Magazine." Various modes have since

been adopted in Britain, in consequence of the increasing popularity of that natural order of trees, the difficulty of procuring seeds of many of them, and the increasing demand for their possession. Engrafting the Coniferae, which a very few years ago was looked upon as requiring skill little short of necromancy, has now become an every-day affair in every respectable nursery establishment. The *rationale*, however, of Tschudy's theory is no doubt the foundation of most of our modern manipulations. The pine and fir tribe is successfully grafted about the middle of June, at which time the young shoots will have attained somewhat more than half their year's growth. An inch or two of the top of the shoot, the leader being preferred, should be cut off; the leaves to the extent of 3 inches should be cut off, leaving, however, a pair of

Fig. 110.

GRAFTING CONIFERS.

Fig. 111.

SIDE-GRAFTING  
CONIFERS.

leaves, fig. 110, opposite and close to the section or point where the shoot was cut over: these, being retained, will draw nourishment to the extremity of the stock before the scion becomes fully attached. The shoot is then split down between the pair of leaves to the depth of 2 inches, and the scion, which, in our example, is that of *Abies morinda* (the stock being *Pinus cembra*), having its lower leaves cut off, and a thin portion of its sides pared off, is inserted to the full depth of the incision in the stock, in the same manner as in cleft-grafting. When the scion is much smaller than the stock, as in our example, the scion is kept close to the side of the stock, so that the bark of both may unite. Two scions, one on each side, may be put on, one of which may be cut away afterwards, should both take—the two giving a double chance of success.

The usual process of tying the graft and claying completes the operation, or, in the case of feeble subjects, grafting-wax may be employed as a substitute for clay.

Fig. 111 shows a variety of wedge or side grafting, we believe first practised by Mr Barron at Elveston, and successfully employed in the case of coniferous trees. The scion in our example, fig. 112, is the Deodar cedar, and the stock the *Pinus cembra*. Mr Barron used the cedar of Lebanon as a stock. He also used scions of

the preceding year's wood, and inserted them in wood of one or two years' growth. We have

Fig. 112.

SCION OF CONIFER  
PREPARED FOR  
GRAFTING.

found, when the stock was strong, as the leading shoot of *Pinus cembra*, or other similar growing Conifera, that the current year's shoot, when about three parts grown, is admirably suited for the purpose; and also, as in our illustration, when the scion has grown to about the length of 2 inches, and with 2 inches of last year's wood—which latter is inserted in the young wood of the stock, cutting the latter quite through the pith to the depth of  $1\frac{1}{4}$  or 2 inches, and securing it in the usual manner. The *Pinus cembra* may be objected to by some, on account of its less robust growth; but the same success has followed when the common spruce, and even the Scotch fir, have been used.

Grafting coniferous trees is a process had recourse to mainly to multiply the rarer species and varieties of which seeds are difficult to procure. So far as perpetuating some of the rarer species to fill up the blanks in botanical and systematic collections, until others originated from seed can be obtained, we see no great harm in having recourse to this mode of propagation; but here the limits of that species of increase should cease. Some have endeavoured to promulgate the theory that grafting has the effect of rendering certain species—those from Mexico, for example, which are too tender to stand our northern climate—more hardy, if wrought on hardy and free-growing stocks; a doctrine we cannot by any means subscribe to, more than that the same operation would have the effect of causing trees of this order to assume the longevity, size, and full development of those originated from seeds. Such, however, is at present the rage for pines, that a glance at the stocks most fitting for the purpose of grafting may not be considered out of place here. The larch has been long used as a stock for the decidar, on which it takes readily; but seeds have been so abundantly imported of that magnificent tree, as to render both the process of grafting, and striking it from cuttings, obsolete matters. The cedar of Lebanon has been also employed for the same purpose, but the stocks in this case are as valuable as the species to be wrought upon them. The Scotch fir (*Pinus sylvestris*) makes a good stock for *Pinus Banksiana* and its congeners. *Pinus austriaca* (the Austrian pine) is probably the best stock for the majority of the tribe; it is a free grower, and transplants well, even when of a considerable size. The Weymouth pine (*Pinus strobus*) has been recommended as a stock for *Pinus Lambertiana*, *P. monticola*, and those allied to them; but who would think of choosing as a stock a tree that is by no means adapted to our climate?—indeed, so much so, that few good specimens of

it are to be even met with. The pinaster (*Pinus pinaster*) is a stock on which *Pinus Lemniana* and its allies will take freely and grow rapidly for a time; but the days of this, as of all other grafted pines, are few, compared with those originated from seed. The spruce fir forms the general stock for the section of Abies; while *Juniperus Virginiana* (the red cedar) is suitable to the whole of the free-growing junipers, and many of the cypresses also; and the common yew to the whole genus Taxus: the more delicate species, however, will succeed better on stocks of the upright or Irish variety.

*Grafting soft-wooded or succulent plants.*—The object here is more of an ornamental than a useful character. The beautiful *Epiphyllum truncatum*, *Russellianum*, &c., are slow-growing plants on their own roots, but become exceedingly beautiful when grafted on the tall and stronger-growing species of Cacti, such as *Pereskia*, *Opuntia*, *Cereus*, &c. The operation is simple, and requires the scions to be taken just as they are beginning their growth: they are inserted in the stocks by simple incision, and secured, for a short time, from falling off by a slight bandage of matting. They are found to succeed best when placed in a rather shady place till adhesion takes place.

Many varieties of pelargonium may also be wrought on the same stock, which, for conservatory specimen plants, has a pleasing and rather novel appearance. The cleft mode of grafting is adopted generally on the Continent, choosing the stock and scion of nearly the same size, and placing them under a glass shade; or if large, in a close somewhat shaded place for a few days. About fifteen days in general effect a union of the parts. According to a paper in the "Révue Horticole," it would appear that grafted pelargoniums have continued healthy for many years.

*Inarching, or grafting by approach*, differs only from most kinds of grafting we have referred to, in having the scion still attached to the parent tree, from which it is deriving support until the union with another takes place, when it is separated entirely. Professor Thouin enumerates thirty-seven varieties of this mode of propagation. These, however, may practically be reduced to two—namely, crown inarching and side inarching, the former having the head cut off at the time of operating, and the latter retaining the head for a time. The spring is the season for performing this operation generally, but any season when the sap is in proper condition, as may be the case in hot-houses, is equally proper. This species of grafting is the only one to be met with in nature, and that only in the case of plants of near propinquity; it may also have given the first idea of grafting to man. Inarching is productive of the same effects as grafting, in inducing an early disposition to fruit-bearing; it is also applicable to plants that are difficult to propagate by other means.

*Method of performance.*—For this purpose it is necessary that the plants to form both the stock and scion should be either growing near to each other, or, if in a portable state, placed so that their branches may meet. A portion of

the bark is then removed from each at the intended point of union, say from an inch to three inches in length, according to the size and strength of the subjects; these parts are fitted together so that the inner barks of both coincide, and the process of tying and claying or waxing follows as in common grafting. Some, however, tongue the scion and stock in the same manner as is done in tongue-grafting. In either way the cambium shortly becomes developed, the alburnum of the scion and stock becomes united; and when this is accomplished, the scion may be cut off a little below where it is united to the stock, either at one operation, or only partially cut through first, and in a few days completely severed. A week or two after the union has taken place, the remaining portion of the scion, if any was left on when separated from the parent plant, should be cut off close to the stock, that the wound may heal over, and leave the stem as perfect as possible. Side inarching without tonguing is well adapted for young shoots of camellias, oranges, &c.; and when the wood of both scion and stock is soft, and full of sap, a union speedily takes place. Tongue inarching is useful when both or either stock and scion are more fully matured, and are somewhat hard and dry.

*Inarching with partially-nourished scions* only differs from the modes we have described above, in having the lower end of the scion inserted in a phial or bottle of water. This water should be changed from time to time, and at each renewal a very thin slice should be removed from the scion, by which its vessels will be kept open, and be able to draw up sufficient support to the graft until adhesion has taken place. Sometimes the end of the shoot is placed in a pot of damp soil, and at others stuck into a potato or turnip.

*Grafting-clay* is prepared by mixing three parts of strong clay with one of horse or cow dung, separated from straw or litter, but having a small quantity of hair, such as is used in preparing plaster lime, mixed with it, to render it more adhesive and less liable to fall off. This mixture should be well incorporated and spread out on a hard flooring, and beaten with mallets or clubs, turning it frequently and giving a little water, and beating again until reduced to a very strong plaster, and fit for being put on with the hands, and for remaining on both in wet and dry weather without crumbling or cracking. The addition of the hair will be found better than using straw or hay, as is usually done. Some recommend the addition of a little salt, with a view to preserve the moisture, which, if not too abundantly applied, may have its advantages.

*Grafting-wax.*—Of this there are many forms, the principal of which are wax and rosin, wax and pitch, tallow and rosin or pitch melted together, and used in a melted but not in a very hot state. Sometimes these are applied in the form of dough or putty; at other times they are spread on paper, cotton, linen, &c., and cut into narrow strips. For very delicate plants the latter forms are the best, and we believe that, for ordinary purposes, for exotic plants, cobblers' wax is better than any, as it can be applied in a cold state; whereas the heat at which most of

the others will be of sufficient consistency and ductility for putting on must be too great for very tender plants, more especially when in a soft and herbaceous state. One of the best preparations for this purpose is that recommended by Mr Powell—viz., 1 lb. of pitch, 1 lb. of rosin,  $\frac{1}{2}$  lb. bees'-wax,  $\frac{1}{4}$  lb. hogs' lard,  $\frac{1}{4}$  lb. turpentine, melted and mixed well together; this composition to be, while in a fluid state, spread upon sheets of moderately thin brown paper, which, when cold, is to be cut into slips about three quarters of an inch in breadth. The scion, when fitted to the stock, is to be wound round with one of these slips, which, when breathed upon, becomes soft and limp, and when cold, sufficiently adhesive to remain on until purposely taken off. Plastic wax, which is as pliable as the last, is thus prepared: Common sealing-wax, any colour except green, one part; white wax, one part; mutton fat, one part; and honey, one-eighth of a part. Melt the fat and white wax first, add the sealing-wax gradually in small pieces, and lastly, put in the honey just before taking it off the fire; pour it into tin moulds, and keep shaking it till it begins to congeal. When breathed upon, or similarly slightly heated, it is fit for use.

In grafting, there are certain important requisites which must be attended to, whatever mode of performing the operation may be adopted. These requisites are thus noticed by Professor Balfour, in his recently published excellent "Class Book of Botany," p. 659: "In the case of dicotyledonous trees, care must be taken to bring the growing parts into contact—the two alburnums and the two libers. We cannot expect that the old wood of trees, in which the active processes of plant life have ceased, will unite. The plants on which grafting is practised must be botanically allied, or, at all events, there must be a similarity in the composition of their sap. Union may take place between plants which, in their natural state, require the same chemical ingredients in the same proportions. This is generally the case with varieties of the same species, more rarely with plants of different species, and least frequently with such as belong to different genera. The lemon may be grafted on the orange, because, as Lindley says, the sap of the latter contains all the earthy and saline substances which the former requires, and can supply them in sufficient quantity to the engrafted twig. But the fig or the grape would not flourish and ripen fruit on the same stock, because these fruits require other substances than the root of the orange extracts from the soil, or in greater quantity than the sap of the orange can supply them. The sap of the stock, in order that grafting may be successful, must contain all that the engrafted bud or shoot requires in every stage of its growth. If the potash or lime required by the grape be not taken up, and in sufficient quantity, by the root of the orange, it will be in vain to engraft the former upon the latter, with the hope of its coming to maturity or yielding perfect fruit. Grafting of varieties on the stem of the species whence they are derived is very common, and is con-

stantly practised with roses, camellias, apples, &c. Species of the same genera are also frequently united. The peach may be grafted on the almond, the apricot on the plum, the plum on the cherry, and the pavia on the horse-chestnut; but the operation will not succeed between the horse-chestnut and the almond. Genera of the same natural order also may sometimes be united: thus, the pear may be grafted on the quince, or on the thorn, or on the amelanchier, all of these belonging to the natural order of Rosaceæ. The lilac is said to adhere to the ash and to *Phillyrea latifolia*; the olive to the ash; and the chionanthus to the ash and lilac—all belonging to the natural order Oleaceæ. The chestnut may be grafted on the oak, in the family Amentiferæ; and *Bignonia radicans* on Catapala, in Bignoniaceæ. There are marked instances of plants which seem to be allied, and yet which cannot be grafted on each other. Thus chestnuts will not graft on beeches, nor apples on pears. As regards the persistence of leaves, it is generally necessary that the plants should correspond; but to this there are exceptions. Some evergreens can be grafted on deciduous plants. *Prunus laurocerasus* and *P. lusitanica* (the Portugal and common laurel), both evergreens, live for some time grafted on the bird-cherry, and are less sensible to cold than those growing on their own roots. *Eriobotrya japonica* and *E. glabra*, also evergreens, live for a very long time grafted on the hawthorn. The cedar of Lebanon, grafted on the common larch, lives upwards of ten years, but it remains stunted and dwarf." The instances of parasitic plants, like the loranthus, mistletoe, &c., adhering to other plants of widely different genera, cannot be fairly stated as exceptions, as the process by which they adhere is not common grafting. "The seeds, and not the buds or slips, are applied to the stems on which they grow, and certain root-like processes are sent inwards." Mr Beaton, Mr Moss, and others, have stated that buds or slips of mistletoe have been made to adhere.

Grafting has the effect of causing some plants to become more hardy and others more tender, and also of causing plants to produce their flowers and fruit at an earlier period of life than were they at once originated from seed; and Knight thought that the fruit upon grafted trees ripened earlier in the season than on trees of the same age, and of the same kind, not grafted, or even grafted upon stocks of their own species; and that the growth and vigour of a tree, and its power to produce successive heavy crops, are diminished apparently by the stagnation in the branches and stock of a portion of that sap, which in a tree growing upon its own stem, or upon a stock of its own species, would descend to nourish and promote the extension of the roots. When the stock is by nature weaker than the scion, or incapable of supplying it with as great an amount of sap as if the supply was derived from its own roots, without any such interruption, then the tree grafted will be limited in the period of its existence in proportion to the scanty supply of sap; and on the other hand, the scion of a weakly variety

will gain strength and increased longevity when worked upon a stock capable of supplying it with as much or a greater quantity of sap than its roots would supply. But much of all this depends on the accuracy of the operation, for a weakly scion may be inaccurately fitted to a stronger stock, and hence an interruption to the ascent of the sap will take place, and consequences directly opposite to what is anticipated are certain to ensue. It is, therefore, probable that it is more owing to the bungling way in which the operation is performed that grafted plants and trees so frequently die a year or two after they have been grafted, and that some others, although they may continue living for a greater number of years, fail in assuming a robust and healthy appearance. The nature of the sap, in some trees, may have its share in this; and it is probable that to either or both of these may be attributed the repeated failures in securing healthy and robust young trees in the order Coniferæ.

Monocotyledonous plants were long considered as incapable of being grafted. Signor Calderini of Milan published, in the "Annales des Sciences Naturelles," an account of some experiments he made on grasses of different species. This experiment was made with a view to improve the vigour of delicate and tender varieties, by grafting them on more robust stocks; and in this he succeeded. The *modus operandi* was from having observed that these plants have at each knot a shoot enclosed in the sheath of the leaf, which can be easily drawn out while the plant is young. He introduced some of these into plants of the same species, having previously removed their young shoots, and found that half of them succeeded. The experiment, we fear, goes no further than to resolve a physiological problem, which is in itself sufficiently interesting: the practical advantage appears to us to be very slight.

#### § 4.—PROPAGATION BY BUDDING.

*Budding* is the operation of transferring the buds of one tree to the branches of another; and its use is the propagation of plants which could not be effected at all, or much less conveniently, by the other modes of extension, such as striking by cuttings, grafting, &c., as well as multiplying a species or variety more expeditiously than by either of the other modes of propagation—as one bud in this case is sufficient in itself to form the future plant, when planted on the alburnum of another of the same or very nearly allied species, while several buds are required in all other methods of propagation. In transferring the bud of one plant to the wood of another, they become vitally united together, as in the case of grafting, which can only be regarded as budding in another form. This process is chiefly employed on woody plants and trees, although it is sometimes performed upon herbaceous plants also, but never on annuals. The varieties of budding are numerous,—much more so than useful. Professor Thonin enumerates twenty-three methods by which the operation is performed; and it is probable that

ten or a dozen more have been added since he wrote. These for the most part owe their origin to foreign cultivators, who are not only expert in performing the operation, but attach considerable importance to some or other of the various modes. Few comparatively of these are practised by the British gardener, who very judiciously calculates more on success than on manipulations from which apparently little is to be gained. All the modes are, however, based upon the same principle—viz., the union between the bud and stock, which takes place, in the first instance, in consequence of the exudation of organisable matter from the soft wood or albumen of the stock; and that union is rendered permanent and complete by the returning sap from the leaves of the stock, or from those of the shoots made by the bud.

The rationale of budding has been thus laid down by Mr George Lindley, in "Guide to the Orchard:"—"Budding differs from grafting in this, that a portion of a stem is not made to strike root on another stem, but that, on the contrary, a bud deprived of all trace of the woody part of a stem is introduced beneath the bark of the stock, and there induced to strike root. In this operation no care is requisite in securing the exact contact of similar parts, and a free channel for the transmission of the roots of the bud between the bark and wood of the stock; for, from the very nature of the operation of budding, this must of necessity be insured. The bark of the bud readily coheres with the wood of the stock, and secures the bud itself from all accidents or injury. But if precautions of the same nature as in grafting are not requisite in budding, others are of no less moment. It is indispensable that the bud which is employed be fully formed, or what gardeners call ripe. If it is imperfectly formed, or unripe, it may not be capable of that subsequent elongation upwards and downwards upon which the whole success of the practice depends. Secondly, great care should be taken, in raising the bark of the stock for the insertion of the bud, that the cambium be not disturbed or injured. The cambium is a secretion between the wood and bark, not only destined to support the descending fibres of the buds, but also to generate that new cellular substance within which the descending fibres are finally found imbedded.

"If, in the preparation of the bark for receiving the bud, this cambium be injured or disturbed, it becomes much less capable of effecting the cohesion that is necessary than if uninjured. In budding, therefore, the bark should be carefully *lifted up*, and not forced from the wood with a bone or metal blade, as is usually done; for although it is no doubt true that an operation clumsily performed will often succeed, yet it should be remembered that, if skilfully managed, it would be attended with much more success; and that a habit of continually operating with delicacy will enable the gardener to succeed with certainty, in cases in which a bungling practitioner would be sure to fail."

Besides the mere purpose of propagation, budding induces important changes in the condition of plants; as, for example, buds trans-

ferred from a seedling tree or shrub, and placed on one of greater age, will produce fruit and flowers sooner than if left on the parent plant. Weak-growing plants, budded on stocks of a stronger character, become strengthened; and hence the weaker-growing vines attain greater strength when budded on the Nice or Syrian. The double yellow rose, which seldom flowers naturally, will do so if budded on some of the stronger-growing China varieties; and almost all weak-growing plants, if wrought upon stronger-growing ones of the same species, will be equally strengthened.

Almost all buds are formed at the axle of the leaves or extremity of the branches, and contain the rudiments of future leaves, branches, or fruit, as well as in many cases the means of propagation. Buds do not spontaneously disengage themselves from the plant to form new individuals, but they may be taken off by man, and artificially made the means of producing future plants. When buds are situated as above, they are called normal or irregular buds, to distinguish them from those that are placed around the collar of the plant, upon the leaves or stem, or otherwise not being axillary or terminal, and which are called adventitious. Some plants do not produce buds, such as annuals; and even many trees in tropical countries are equally destitute of them, while in cold countries they universally exist.

*The season for performing the operation of budding is in spring, when the sap is rising, and in the end of summer—say July or August—when the sap is descending. In the former case the inserted bud develops itself immediately, while in the latter this development does not take place till the spring following. At other seasons, also, the operation has been successfully accomplished, much depending on the kind of tree, and also on whether it be an early or late season. In budding at an early season, it is of importance to insert the bud with the whole of its wood attached; but as the season advances, and the buds have attained their full maturity, the less of this woody matter that is retained the better. "Budding in spring or early summer is generally accompanied, it may be presumed, by a copious current of sap. Not so, however, late summer-budding on all occasions; for the season may have been unusually warm and dry, the stock may be short of sap—or, in other words, be beset with a paralysed root action. All these are impediments. A copious watering the evening previous to the process will, however, promote the free rising of the bark, on which so much depends. In addition to this, a cloudy day is preferable to a sunny one."*—*Cott. Gard. Dict.* Mild cloudy weather is in general preferred for this operation, because the viscous surfaces exposed to the air are more liable to be dried up by evaporation, by which the healing process is retarded, if not entirely prevented; besides, in dry windy weather the bark will not rise so well. This opinion has, however, been of late questioned by Mr Saul of Bristol, who says, in the "Gard. Mag. of Botany," "that in warm weather the sap is more gelatinous; and the bud, on being extracted and inserted in the

stock quickly, properly tied, &c., adheres more readily. On the contrary, in wet cloudy weather the sap is more thin and watery, and the bud will not unite so freely." To this he adds, "that a fall of rain—likely in such weather—after the buds are inserted, will fill up the incisions, and thereby rot and perish the buds before they have time to unite with the stock. Not only is clear weather best for the experienced budder, but likewise for the amateur and tyro."

Much of the success depends on the state of the bud. "The mature bud," Mr T. A. Knight, in "Transactions of the Horticultural Society," vol. iii. p. 136, observes, "takes immediately with more certainty, under the same external circumstances; it is much less liable to perish during winter, and it possesses the valuable property of rarely or never vegetating prematurely in the summer, though it be inserted before the usual period, and in the season when the sap of the stock is most abundant. I have," he says, "in different years, removed some hundred buds of the peach-tree from the forcing-house to luxuriant shoots upon the open wall; and I have never seen an instance in which any of such buds have broken and vegetated during the summer and autumn. But when I have had occasion to reverse this process, and to insert immature buds from the open wall on the branches of trees growing in a peach-house, many of these, and in some seasons all, have broken soon after being inserted, though, at the period of insertion, the trees in the peach-house had nearly ceased to grow." The season of budding, or rather the state of the plant, is of primary importance in securing success. "Buds should either be inserted," says Dr Lindley, in "Theory of Horticulture," p. 244, "when the vegetation of a plant is languid, or growth above the place of insertion should be arrested by pinching the terminal bud; otherwise the sap which should be directed into the bud, in order to assist in its adhesion, is conveyed to other places, and the bud perishes from starvation. For similar reasons, when a bud begins to grow, having firmly fixed itself upon the stock, the latter should be headed back nearly as far as the bud, so as to compel all the current of sap to flow towards it, otherwise the buds of the stock itself will obtain that food which the stranger bud should be supplied with."

Much of the success in budding depends on the condition of the bud at the time of its insertion; yet even as to that condition opinions are by no means agreed. We have stated that such buds as appear to have lost their root or heart by the operation of extracting the woody matter under them, are useless, and should be discarded. This is denied by Mr Lymburn, who asserts that blind buds owe their origin to the bud itself being diseased, more than to the supposed injury they sustain in the removal of the piece of wood connecting the bud with the alburnum. A writer in "The Gardeners' Chronicle," 1842, on this matter remarks: "The bud will sometimes take although the heart appears to be gone; it will sometimes adhere and start quickly, although more wood be left in the shield than will allow the sides to lie flat down; but the

evident desideratum is, that no more of the wood adjacent to the eye be left than will secure its close attachment to the shoot upon which it may be placed, nor any less than may suffice to retain the growing principle, the limit of which must be defined by a combination of theory and practice, and at present remains a problem to be solved. Many buds have I inserted, in which the eyes have not been sufficiently swollen, and no produce has come forth; and many a bud have I inserted, in the hope that the cambium would fill the vacant hole, which fear told me was too large, yet which a scanty supply of buds induced me to retain—but all in vain; for though the bark adhered the eye was lost, and many a wood bud inserted thus has become dry before it could adhere. I believe the great secret to be, taking the bud in its proper state—*i. e.*, full formed (not too near the base of the stock, from which it will part with difficulty, nor too near the top, because insufficiently ripe)—and to insert it when the receiving plant and the weather are in a favourable state to continue the elaboration of those juices necessary to form a junction. The period of the year is, comparatively speaking, immaterial. I have inserted buds at all times, and have now in my possession a plant that was worked on the 21st October, ten years ago. Shoots that grow angularly, and are nearly the same size all the way up, afford better buds than such as are produced on long rapid-growing branches: the buds on the latter are seldom well defined, and if inserted at all hollow in the centre, are sure to go blind."

*Peculiar advantages of budding.*—To those noticed above we may add the facility that the process affords of producing a shoot in almost any part of the tree, at the will of the operator, where, without this transplanting of a bud, no branch could be induced to form. Many varieties may by this mode be made to grow on a single tree, which no other species of grafting could effect so completely. Many stone-fruits are multiplied by this means, which could not be so successfully accomplished by the other species of grafting. And, lastly, the buds of young fruit-trees, when transplanted to the branches of full-grown ones, will be induced to produce their fruit, which, if left on the parent stem, might not do so for years. Mr Knight, by transferring the blossom buds of an abundant fruit-bud-producing tree to the branches of those which do not show these organs so profusely, or even sparingly, caused excellent crops of fruit thus to be produced on the latter.

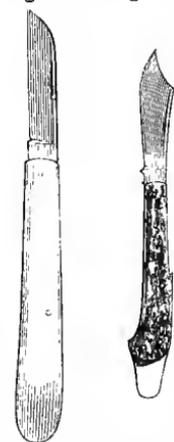

*Natural advantages of budding.*—Trees propagated by this means are thought to be of longer duration than those that are grafted; they also are in general two years longer in producing fruit than grafted ones of the same species. The process is employed on most stone-bearing fruit trees, as in their case grafting is apt to bring about a disposition in them to throw out gum at the point of union. Trees, also, which may have failed to take by grafting in spring, may be budded in July or August—an important matter in fruit-tree nurseries. Most woody plants may be multiplied by budding, many of which could not be operated on by grafting.

*Preliminary process.*—The state of the bark, both in the bud and in the stock, must be attended to, as the bark in both cases must separate freely from the wood beneath; for if either be unfit in this respect, there will be little chance of success in the operation. This is best ascertained by making trial incisions, and if both are found in a proper state, operations should be at once commenced. If the bark do not rise freely, the process should be delayed for a few days; and this state will often be accelerated if copious supplies of water be given at the roots, more especially in hot dry weather. The buds are then to be cut from the parent tree, *not individually*, but the shoots of the current year on which they are growing are to be removed, their leaves cut off, leaving a part of the leaf-stalk to each, to serve as a handle in inserting the bud, as well as to act as a protection to it. The reason for cutting off the leaves is to prevent the loss of sap by evaporation; and branches so treated may be sent to a great distance without injury to the vitality of the buds, if they are carefully packed in an air-tight case. While the operation of making the incision for the bud in the stem of the stock is going on, the cuttings should be placed handy, kept under shade, and with their lower ends in a pan of water. As each incision is made a bud is cut from the shoot, and when prepared, is inserted as quickly as possible, and fixed by coiling a strand of fresh matting, &c. around the bud and stock—which matting should be kept in a moist state, and handy to the operator. Such arrangements are necessary in most sorts of budding.

*Shield-budding*, in one or other of its modifications, is that most generally practised in Britain, and, with flute-budding, may be said to embrace all the modes of the operation really useful.

*Shield-budding in spring* is much practised by the Continental cultivators, and is found expedient at other seasons, in the case of roses, camellias, and many other flowering plants. For

Fig. 113. Fig. 114.

COMMON AND FRENCH BUDDING-KNIVES.

deciduous trees like the apple and pear, the buds are selected in autumn, and kept during winter attached to the shoots they are produced on, by placing their ends in the ground, as is usually done in the case of scions for grafting. In spring, when the sap is up in the stock, the buds are taken from the cuttings, and inserted in the following manner: A transverse cut is made by the common or the French budding-knife, figs. 113, 114, in the shoot containing the bud, a little below an eye; and this transverse cut is met by a longer incision downwards, commencing a little above the eye, taking great care that

a portion of the wood is removed with the bark in which the bud is situated. The bark of the stock is then cut in manner resembling an inverted T; the greatest care should, however, be taken that the edges of both the cuts in the stock and bud be cut clean, so that they shall, when brought

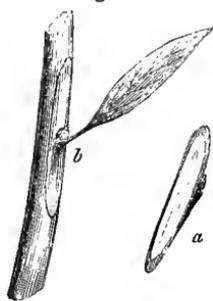

Fig. 115.

SHIELD-BUDDING THE ROSE.

together, form a speedy and uniform union. In the case of the rose, the stock should be pruned down about eight days after the bud is inserted to the shoot above it on the opposite side of the stock, which shoot should be shortened by being pinched back to two or three eyes, removing at the same time all the side shoots as they are produced; and when the shoot formed from the bud has extended to its fifth leaf, the point should be pinched off, which will cause it to branch out, and, in all probability, induce it to flower in September of the same year. The rose is also budded in spring, even before the sap rises in the stock, in the following manner: A niche is cut out of the stock, say an inch or so in length, as in fig. 116. A bud is taken of the same size and form, retaining a small portion of the wood; the bud is then nicely fitted to the niche, and secured by coiling a strand of soft

Fig. 116.

SHIELD-BUDDING THE CAMELLIA.

matting round it. In the same manner the camellia, orange, and rhododendron may be budded, only in their cases the entire leaf should be left attached to the bud. A modification of this manner is often resorted to in the case of the latter plants—namely, by taking a bud, *a*, with a portion of the wood attached to it, and cutting out a similar piece from the stock, *b*, and substituting the one for the other.

In the case of some very delicate plants, cotton wool or very soft moss is placed round the bud, and secured by passing a strong thread round it, to keep it firmly in its place. In ordinary cases, however, the expert budder uses nothing but fine strands of bast matting, and the success as well as the expedition with which this nice operation is performed in our British nurseries is truly wonderful.

The rationale of budding is thus clearly

explained by Dr Lindley, in "Theory of Hort.," p. 223: "By these means we gain the important end of bringing in close contact a considerable surface of organising matter. The organisation of wood takes place on its exterior, and that of the bark on its interior surface, and these are the parts which are applied to each other in the operation of budding; in addition to which the stronger bud finds itself in its new position as freely in communication with alimentary matter, or more so, than on its parent branch. A union takes place of the cellular faces, or horizontal system of the stock and bark of the bud; while the latter, as soon as it begins to grow, sends down the woody matter or vertical system through the cellular substance. In consequence of the horizontal incision, the returning sap of the scion is arrested in its course, and accumulates just a little above the new bud, to which it is gradually supplied as it is required. Sometimes the whole of the wood of the bud below the bark is allowed to remain; and in that case contact between the organising surfaces of the stock and scion does not take place, and the union of the two is much less certain. As it is, however, usually practised with tender shoots before the wood is consolidated, the contact spoken of is of less moment. In all cases, a portion of the wood of the bud must be left adhering to it, or the bud will perish; because its most essential part is the young woody matter in its centre, and not the external surface, which is a mere coating of bark." This shows the necessity, in carefully removing the woody part of the bud, of preserving the root, as it were, of the bud itself, as has been already said.

The Americans do not extract the wood from the bud, but leave it in as cut from the shoot, and this may possibly suit their hot, dry climate; but from experiments made by Mr Saul of Bristol, who has practised both methods in the extensive nurseries at Durdum Downs, his conclusions are in favour of the English mode—namely, of extracting the wood from the bud. Sometimes, he says, there may be an advantage in putting in the wood—namely, when the shoot has become firm, and the wood and bark will not freely separate; then, if inserted in a free-growing stock, it will in all probability take. The evidence of both writers and practitioners in both countries is so divided upon this subject, that we shall here transcribe the American practice, as given by Mr Downing, one of their best authorities, in his useful work, "Fruits and Fruit Trees of America."

*American shield-budding.*—"Having your stock of buds ready, choose a smooth portion of the stock. When the latter is small, let it be near the ground, and, if equally convenient, select also the north side of the stock, as least exposed to the sun. Make an upright incision in the bark from an inch to an inch and a half long, and at the top of this make a cross cut, so that the whole shall form a T; from the stick of your buds (your knife being very sharp) cut a thin smooth slice of wood and bark containing a bud; with the ivory heft of your budding-knife now raise the bark on each side of the incision just wide enough to admit easily the

prepared bud. Taking hold of the foot-stalk of the leaf, insert the bud under the bark, pushing it gently down to the bottom of the incision. If the upper portion of the bud projects above the horizontal part of the T, cut it smoothly off now, so that it may completely fit. A bandage of soft matting is now tied pretty firmly over the whole wound, commencing at the bottom, and leaving the bud and the foot-stalk of the leaf only exposed to the light and air." Mr Downing continues: "The American variety is found greatly preferable to the European mode, at least for this climate. Many sorts of fruit trees, especially plums and cherries, nearly mature their growth, and require to be budded in the hottest part of our summer. In the old method, the bud having only a shield of bark, with but a particle of wood in the heart of the bud, is much more liable to be destroyed by heat or dryness than when the slice of wood is left behind, in the American way. Taking out this wood is always an operation requiring some dexterity and practice, as few buds grow when their eye or heart wood is damaged. The American method, therefore, requires less skill, can be done earlier in the season with younger wood, is performed in much less time, and is uniformly more successful. It has been very fairly tested upon hundreds of thousands of fruit trees for the last twenty years; and although practised English budders coming here are at first greatly prejudiced against it, as being in direct opposition to one of the most essential features in the old mode, yet a fair trial has never failed to convince them of the superiority of the new."

*Saul's new method of shield-budding.*—"In budding," says this cultivator, "the top bud on the shoot should be commenced with, cutting from about an eighth of an inch below the bud or eye, to from half an inch to an inch above it, in order that there may be a sufficiency of bark to hold with the fingers without rubbing the portion which is to be inserted; take out the wood as already recommended; next make an incision in the shoot of the stock close to the main stem, and about half an inch long—this is long enough; cut across at top, raise the bark with the end of the budding-knife without bruising it, and insert the bud. It is now to be tied with a little worsted or cotton. One tie below the eye and two above will be ample, as its entire length will not be more than half an inch, and a quarter of that below the eye. The most inexperienced amateur need not give more than two rounds below the eye and three above; but the practical workman will find the number I have mentioned sufficient."

*Shield-budding reversed*, fig. 117, is performed by having the transverse cut at the bottom of the perpendicular slit instead of at its top, and of course the shield is reversed in position. This mode is preferred by those who think that the sap rises in the bark equally with the wood; but as this opinion is not fully entertained, the process is seldom used in this country, although very generally in the south of Europe, particularly in the propagation of orange-trees. It is admitted to be suitable for trees having gummy sap. For the same purpose budding with the

eye turned downwards has been recommended. But its most important use is to induce a state of productiveness in fruit trees. In consequence of the bud being placed with its point downwards, an interruption takes place in the flow of the sap. This effect is denied by many, who say the shoots after a time regain their natural position, and hence no such interruption takes place. The shoot, no doubt, the second year, takes its natural upright direction; but the bend, which is always abrupt at the point where it changes from the pendant to the upright, has much the same effect on the sap's flow as that of bending an upright branch downwards, but probably not to the same extent.

*Shield-budding with a terminal bud.*—This mode is sometimes employed in the case of a tree losing its leading shoot, or of a branch meeting

SHIELD-BUDDING REVERSED.

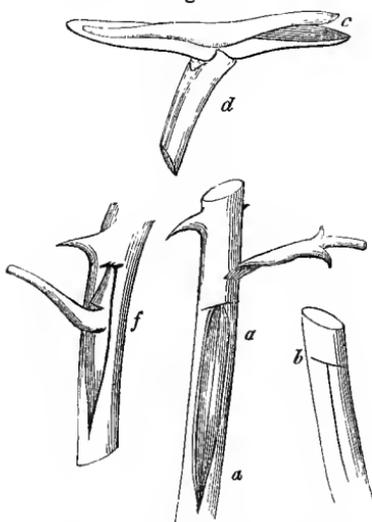

with a similar accident.

*Shield-budding with a view to repair injury done to the bark.*—This is done by paring the edges of the wound smooth, and selecting a piece of healthy bark from the same or from another tree of the same species, of the same shape and size, and covering the wound so exactly that a union takes place and the blemish is repaired. It is difficult to cause adhesion in the case of stone-fruits by this means. It is, however, seldom resorted to.

*Shield-budding the rose* is thus described by Mr Paul, in his beautiful work, "The Rose Garden," p. 131; and as few have succeeded more in the propagation of "the queen of flowers," we present his *modus operandi* in nearly his own words: "The piece of bark is called the bud (*d*, fig. 118), and the tree in which it is inserted is called the stock. In the first place, obtain a shoot from the tree whose identity we wish to perpetuate; from this the leaves are cut off, leaving, however, about half an inch of the leaf-stalk to every bud. Before proceeding farther, the prickles should be rubbed off both stock and scion, that they may not interfere with the operation, or annoy the fingers of the operator. Now take the budding-knife in the right hand, and make a longitudinal cut, *a*, about an inch in length, terminated at the top end, *b*, with a cross cut. In using the knife, take care not to cut too deep: *through the bark* is all that is necessary; deeper is, indeed, injurious. Now turn the handle of the knife to the incision, running it up and down the cut *a*, twisting it slightly on either side, to raise the bark. All is now ready for the reception of the stranger bud. Take the shoot which is to furnish it in the left hand, with the thicker part towards the finger-ends; with the knife in the right hand, commence cutting about half an inch behind the bud, passing the knife up-

wards under the bud, and to about the same distance beyond it. The knife should have a

Fig. 118.

MR PAUL'S METHOD OF SHIELD-BUDDING.

keen edge, that the bark may not be ruffled in the operation. In cutting out the bud, the knife should pass through almost level; it may, however, in some cases dip a trifle, when passing directly under the bud, as the wood before and behind it is not always on the same level. If the bud be cut ever so skilfully, there will be a little of the wood adhering thereto. This some advise the removal of; others say, let it remain. Much depends on circumstances. If the shoot is not fully ripe, or if, from the nature of the variety, the wood is soft when taken, cut the bud as shallow as possible, and place it with the wood in the stock; but the shoot is usually ripe and firm, and then the wood should be withdrawn. To do this easily, place the bud between the fore-finger and thumb of the left hand, with the cut uppermost, and with the upper end pointing from the hand. Insert the point of the knife just beneath the wood, *c*—that is, between the wood and the bark—and by a skilful twist of the knife (which can only be acquired by practice) the wood may be jerked out. Now with the same hand place the bud on the bark of the stock, parallel with the longitudinal incision, and with the upper end towards the top of the shoot; then with the handle of the knife raise the bark on the side opposite to that on which the bud is placed, pushing two-thirds of the bud beneath the bark with the thumb. Now raise the bark on the opposite side, and the bud may be gently pushed under with the handle of the knife, or will probably drop in. When properly placed, the eye of the bud should be directly under the opening caused by the raising of the edges of the bark of the longitudinal incision *f*; if it be not so, the handle of the budding-knife should be inserted beneath the bark, to push it to a right

position. But if the bud be not deprived of the leaf-stalk, if that is allowed to protrude from the opening, the eye will be secured in the best site. After being inserted, the bud should be drawn upwards to the cross cut, and the upper end cut at the same angle, that its bark may abut against the bark of the stock laid open by the cross cut *b*. The bud then is inserted, and it now remains to bind it in. For this purpose, take worsted or bast—the former is generally preferred; commence tying at the bottom of the cut, passing upwards till the whole length of the incision is bound over. Where the buds are feeble, or where success is deemed important, it is customary to tie a little damp moss or a leaf over the bud after the operation is completed, which is in no case objectionable, except on account of the additional time it occupies.

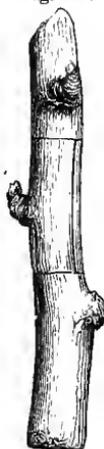

“About three weeks after the operation has been performed the worsted may be removed. If the bud is not well united, let it be tied up *loosely* again; if it is, leave it untied, and there is an end of care till the following spring. In February, the wild shoot may be cut away 2 inches beyond the bud, when the latter will break, and soon form a tree. It is often said that it is unnecessary for the bud to remain so long dormant, and that it may be made to break, and, if an autumnal rose, even to flower, the same year.” Mr Paul admits the truth of this statement, but condemns the practice. “It is accomplished by cutting off the wild shoot a few inches above the bud, or by tying a ligature tightly round it at the same distance. The object sought is to cut off certain channels, through which the sap naturally flows, that it may become concentrated in the vicinity of the bud. The results are usually premature development and an unsound plant. If the buds break soon after being inserted, the shoots are puny and weakly, evidently suffering from want of nourishment. If allowed to lie dormant till spring, they have a rich store of food at their command, and grow with surprising vigour. When a bud has shot a few inches, and formed two or three good leaves, the heart of the shoot may be pinched out, when from the axle of each leaf an eye will in time push forth. In May the stock may be headed down close to where the bud has been inserted; and if the growth be vigorous, the wound made in so doing will quickly cicatrise, and a perfect plant is the result. If the time for budding be demanded, we should give July. It does not, however, require great penetration to see that this point depends in some measure on the season. The practised hand will cut and raise the bark, to ascertain when it parts freely from the wood; the tyro will find a criterion in the prickles. If slight pressure cause them to separate from the bark, the stocks are in good order, and the fitness of the shoots or scions may be ascertained by the same test. If the weather be hot and sunny, morning and evening are the best periods for budding. A July sun pouring down his rays upon the operator is not altogether pleasant, and in regard to the operation, does not increase the chances of success. The shoots

from which the buds are to be taken should not be cut from the tree till we are ready for action, and the less time that elapses between the different branches of the work the better.”

*Scallop-budding* may be performed at almost any season of the year, and also upon trees having thick or corky bark. It is accomplished by taking a thin tongue-shaped section of bark from the side of the stock, and a similar section from the shoot containing the buds, but in neither case removing the wood. The section containing the bud is then laid on the corresponding scallop in the stock, its upper edge exactly fitted as in shield-budding, and at least one of its edges as in whip-grafting. After this it is secured in the usual way.

*Annular or ring budding* is performed either at the period of the first ascent, or at that of the principal movement of the sap in August. The stock and scion are formed as

Fig. 119.

ANNULAR  
BUDDING.

in fig. 119; but in either case the top of the stock is not to be interfered with. This is a valuable mode of propagating trees or shrubs with hard wood and thick bark, or those which, like the walnut, have buds so large as to render it difficult to bud them in the common way. This mode is also of great value, and may be turned to good account, where hares or other vermin have destroyed the bark near the ground, or even for fractured bark upon any part of a tree. Recourse is frequently had to such a process in America, and it is thus described by Downing: “In snowy winters, fruit trees in orchards are sometimes girdled at the ground by field-mice, and a growth of twenty years is thus destroyed in a single day, should the girdle extend quite round the tree. To save such a tree it is only necessary, as soon as the sap rises vigorously in the spring, to apply a new ring of bark, in the annular mode, taken from a branch of proper size; tying it firmly, covering it with grafting clay to exclude the air, and finally drawing up the earth so as to cover the wound completely. When the tree is too large to apply a single ring, separate pieces, carefully fitted, will answer; and it is well to reduce the top somewhat by pruning, that it may not make too large a demand on the root for a supply of food.”

*Flute or tube budding*.—Of this there are four distinct varieties, with several modifications; none are much practised in Britain. Common flute-budding, as will be seen by our figure of annular or ring budding, consists in removing a ring of bark from the stock, and procuring a similar ring of equal size, having a bud or buds, and which is to be fitted to the un-barked part of the stock, making the two barks fit exactly at their point of union. Should the ring to be attached be of rather too large diameter, it may be slit down the middle, and a por-

tion removed, so that, when placed on the stock, it may fit closely; and if too small, it is in like manner slit up longitudinally, to admit of its being put round the stock, and, if properly performed, a piece may be added to make good the deficiency. It is then tied on, and the slit covered with clay or grafting-wax, to exclude the air till adhesion takes place. The operation is generally performed in spring, and considered by the Continental cultivators of advantage in the case of plants difficult to bud by other means. In the south of France, terminal flute-budding is chiefly had recourse to in the case of figs, mulberries, walnuts, chestnuts, &c.

*Terminal flute or tube budding*, fig. 120.—Of this there are several modifications. It is employed in cases of trees that are

thought not to take readily by other means, such as the white mulberry, the walnut, &c. The operation is usually performed in spring, but may also be done in autumn. In the former case, the scions are taken off in autumn, and stuck in the ground in a cool shady place till spring. The scion and stock should be as nearly of the same size as possible, at least the stock should not exceed in diameter the scion, as it is desirable that the ring of bark taken off the latter should completely surround the former. When, however, the ring of bark is larger than the stock to be covered, a small portion of it may be cut out, so as to make the joining of its edges as complete as possible; for it is important that they do join.

Fig. 120.

TERMINAL  
FLUTE-BUDDING.

*Budding with the pushing eye* offers very considerable advantages in the process of rapid propagation. M. Carrière, in "Révue Horticole," October 1852, throws the following light upon this interesting subject. "Let us only see," he says, "how a rose-grower proceeds when he wishes to propagate speedily some new or choice variety. He encourages, by every means in his power, the perfect development of the first young shoots the plant pushes out; and in this he succeeds in obtaining in June, and even sometimes in May, eyes with which he can bud fresh stocks—these eyes, of course, being ready to push into shoots. The plants so budded will supply him, towards the end of summer, with other young shoots furnished with dormant eyes, such as will only push next spring, and with these he can bud more stocks, and obtain plants that will flower in the following season; and by this course, in the space of a year he finds himself in possession of a considerable stock of a variety of which he had only a single plant at the outset." By the same process, M. Carrière observes, other plants can be as speedily propagated, and instances a new variety of lilac, which he had received on the 24th of May, on which day he took off a small shoot from which five buds were wrought. Four of them took

and one of them is now (October) 28 inches long, affording 22 eyes fit for budding, which, if budded now, would produce next spring a score of plants, the produce of one of the buds wrought last May. "Admitting," he continues, "that the success was not always so great, and that each of the four first buds produced shoots having only 16 eyes, still I should next spring find myself in possession of 64 plants."

Of all the varieties of budding, that termed shield-budding, fig. 115, is the most useful, and, therefore, the mode followed most generally in our nurseries. It is now considered pretty generally, amongst practical propagators, to be the most judicious way of multiplying most of the varieties of fruit and ornamental trees and shrubs, and to a very considerable extent has superseded propagation by grafting. The season for performing the operation, as has already been remarked, extends over a considerable period, depending much on the kind of tree and condition of the wood; and the only rule that can be laid down in this case is, that the buds should appear plump, fully and perfectly formed in the axles of the leaves, and the bark rising freely in the shoot into which the bud is to be inserted. This state depends upon the free ascent of the sap; and hence, as has been suggested by Mr Saul, mild and warm weather is to be preferred to a dull and cloudy state of the sky for performing the operation. Hardy evergreens take freely if budded in June, selecting buds from shoots of the preceding year's growth, and inserting them in the stock without removing the wood, as is usually practised with deciduous trees. Towards the end of June and beginning of July, the most forward in growth of deciduous ornamental trees and shrubs should be proceeded with, taking the buds from the most advanced shoots of the present year's growth. From the beginning of July to the middle of August, stone-fruits and pears, with the exception of the peach and apricot, may be successfully wrought; and during the latter end of August and beginning of September, peaches, apricots, and apples will be in a fit condition for budding.

Many other modes of budding might be described—the above may be taken as the principal.

The part of the stock into which the bud is to be inserted demands consideration. In a leading article in "The Gardeners' Chronicle," 1842, this matter is very clearly explained. "When first inserted, the bud is mainly nourished by matter sent down from the leaves of the stock; it should therefore be introduced near the lower end of a shoot, and not near the point. The number of buds to be put into the same branch is no further material, than that many incisions in the same branch will have the effect of impairing its general health. As the young bud is to be nourished at first by the leaves above it on the stock, the best place to insert it is close beneath some leaf in full activity; it is not, therefore, the most open and smooth part of the stock that is to be selected (although we see this daily done) when a choice can be made. For the same reason, it might appear injudicious to shorten the branch into

which a bud is inserted; but if the shoot is not stopped, the rising sap will be attracted into the youngest leaves, and expended in their increase; while, on the other hand, if the shoot is stopped, the sap will be forced laterally into the buds already forming on its sides, and the new bud will participate in this advantage. It is therefore, upon the whole, advantageous to cut off a part of each shoot into which a bud is introduced. The removal of a quarter of it is enough to answer the intended purpose. As it is important in every way that the vigour of the budded branch should be preserved for the buds which are forming, all flowers or fruit should be cut off it, and from the twigs in its vicinity, otherwise these parts will consume the organizable matter which should be applied to the service of the new buds."

### § 5.—PROPAGATION BY CUTTINGS.

The accidental sticking into the ground of a willow twig, or other equally ready-rooting plant, may have taught man the art of increasing by cuttings. Propagation by cuttings, like grafting, by no means constitutes a new plant, but only an extension of the parent from which it was taken, differing in no respect in habit, nature, or property, from it. Many plants originated from cuttings, such as the poplar, vine, elder, willow, &c., attain as large a size and as great an age as if originated from seed; and the first and last of these are almost invariably propagated by this means, and that often when the cutting or truncheon is of large size and considerable age. The oak and beech amongst trees are, however, exceptions to this rule, and it was long thought that coniferous trees were incapable of this mode of increase. Subsequent experience has, however, proved this opinion to be incorrect, for with the exception of *Araucaria excelsa*, *Pinus nobilis*, and a few others, our expert nursery propagators increase this popular family with seemingly little difficulty; and there is no doubt but that plants of this order so multiplied will make more healthy and more durable trees than those propagated otherwise than by seeds. Instances have occasionally occurred of some coniferous trees propagating themselves somewhat in the way of layers or cuttings, as where their lower branches have come into contact with the ground, and been partially by accident covered with soil, they have rooted, and their points taken an upright direction, and when afterwards separated from the parent, have become tolerable trees. These instances are of rare occurrence, but they no doubt first led the observing cultivator to adopt, artificially, a more certain process than was thus pointed out to him by nature.

That portion of a plant or tree selected for a cutting must of necessity contain buds or eyes on its surface to secure its growth, and hence that portion of the stem or branches called the internode—that is, the spaces which intervene between leaf and leaf, or bud and bud, as exemplified in the vine, fig. 121, and which have no buds, as from *a* to *a*—is of all parts the most

improper for the purpose. The vine, and some other plants, when subjected to a humid atmosphere, throw out roots even into the air, but these are always found to proceed from the buds,

Fig. 121.

CUTTING OF VINE.

Dr Lindley observes, "that the roots of a plant are as much productions of buds as branches are, and that the stem is nothing more than a collection of such roots held together, under the form of wood and bark." This is the reason why cuttings should be cut close below a leaf bud; if cut above it on the internode, roots could not be produced. This opinion seems confirmed by the circumstance of the old trunks and larger branches of pear-trees, when blown down, often striking roots at those parts where they come in contact with the ground, as instanced in the celebrated old pear-tree at Holme Lacy, in Herefordshire, and in the case of many others of far less note. Upon carefully examining such trees, it will be found that the roots have emanated from latent buds which, had they not come in contact with the soil, would for ever have remained dormant. And in the very same way, roots were produced

from the under side of the ancient mulberry-tree described by Dr Neill, in "Horticultural Tour," p. 13, as then existing in a garden at Canterbury, and which had been prostrated above a century. Another well-authenticated fact is recorded by Mr Livingstone in the fourth volume of "The Horticultural Society's Transactions," in the case of the *Petrocarpus marsupium*, one of the largest trees of the East Indies, which is "readily propagated by cuttings of all sizes, if planted even after the pieces have been cut for many months, notwithstanding they appear quite dry, and fit only for the fire. I have witnessed," says Mr Livingstone, "some three, four, five, six, or seven inches in diameter, and ten or twelve feet long, come to be fine trees in a few years. While watching the transformation of the log into the tree, I have been able to trace the progress of the radicles from the buds, which began to shoot from the upper part of the stump a few days after it had been placed in the ground, and marked their progress till they reached the earth. By elevating the bark, minute fibres are seen to descend contemporaneously as the bud shoots into a branch." And even chips of such trees as the poplar, having a portion of the bark remaining on them when buried in the ground, have been known to produce roots, and ultimately to become trees—a circumstance noticed by some of our oldest horticultural writers. Of fruit-bearing hardy trees, the vine, fig, mulberry, gooseberry, and currant are for the most part propagated by cuttings. Almost every variety of apple may be propagated by cuttings; the pear less readily; and all other

sorts are so by grafting, budding, suckers, or layers.

*Cuttings of hardy fruit trees* should be taken off any time between the shedding of the leaves in autumn and the first swelling of the buds in spring. The earlier, however, they are taken off and planted after the ripening of the wood the better, as in this case the callus will form at their base during winter, and the roots commence to push out early in spring. A somewhat shaded and cool place, such as behind a north wall, is the most proper; and one exposed much to the sun is the worst that could be chosen. During April and May, while their roots are forming, they will derive considerable benefit from the partial shade of the wall, if not planted nearer it than 3 or 4 feet; while by the end of June, and through July and August, they will enjoy a sufficient amount of sunshine. By the end of October they will be ready for transplanting into nursery lines in the open garden. For the various modes of performing the operation applicable to hardy fruit trees, vide articles VINE, FIG, MULBERRY, GOOSEBERRY, and APPLE.

*Cuttings of hardy deciduous trees and shrubs* are for the most part taken off in autumn, when the wood becomes ripe, and may be either planted at the same time, or laid in pretty thickly in the soil, having one-third of their lower ends covered with earth. In this way space is economised; and as the callosity will form at their root ends, if brought in close contact with the earth, as well in this position as if planted out, they may afterwards be planted when time permits, only the earlier in spring the better.

*Cuttings of Coniferæ.*—Many of these are now found to propagate freely by this means, and many fine plants are already in our collections, even of the very recently introduced sorts, such as *Taxodium sempervirens*, *Cryptomeria japonica*, and the funeral cypress. The hardier and more common sorts, as the *Arbor vite*, Irish or upright yew, Swedish juniper, and many of the small-leaved kinds of pines, if the cuttings are taken off as soon as they have completed their annual growth, and planted in a shady border, or in a pit with a northern exposure, will root freely, and make as good plants as if originated from seed. The following very judicious directions have recently been given by Mr Appleby, in the ninth volume of "The Cottage Gardener," p. 242: "The way to manage Coniferæ is first to prepare a pot to put them in; drain it well, and cover the drainage with a little moss; then fill the pot to within an inch of the top with a compost of loam and sandy peat, mixing it freely with sand; upon this place an inch of pure sand, watering it gently, to settle it and make it firm. Then prepare the cuttings—take them off the tree just at the point where the last made wood joins to the wood made the previous year; trim off, without wounding the bark, the lower leaves and branches, if any, and insert the cuttings in rows across the pot till it is full. The best time to do this is about the month of October, though they will do pretty well up to the March following. Water the cuttings gently, and allow the tops to dry, then place them in a

gentle hot-bed, just warm enough to cause them to form a swelling at the base, but not so hot as to induce shoots, unless the operator has the convenience of a greenhouse to harden them off. They do not require bell-glasses, or at least will root very well without them. In putting in cuttings of Coniferæ in the above manner, I refer more especially to the more rare kinds, such as the *Cryptomarias*, some *Cupressus*, *Taxodium sempervirens*, *Arbor vite*, and some of the genus *Taxus*. Others that are more common may be successfully propagated by cuttings put in early in the autumn, under hand-glasses, on a north-west border, where the sun leaves them about ten o'clock. For such the ground should be prepared in a similar way to that in the cutting-pots, and the cuttings put in by the same method. The hand-glasses should be kept on through the winter, and removed as soon as they begin to grow in spring." This excellent cultivator recommends taking up the cuttings and potting them, and placing them under a cold frame to encourage their free growth, and most wisely recommends their being planted out into nursery-rows before the roots become matted round the sides of the pots. In the case of *Araucaria excelsa*, which is rarely propagated successfully by cuttings, he recommends taking out the central shoot, or main leader, which will induce several other leaders to push up, any of which may be taken off as soon as formed, and put in as cuttings. This will no doubt secure young trees of perfect form, keeping the original as a stock to provide future supplies.

*Cuttings of partially ripened wood.*—In this state most hardy evergreen shrubs are propagated, as well as roses, particularly the China, tea-scented, and most climbing sorts, which, if put in towards the end of summer in a sheltered somewhat shaded place, will form their callosity during winter, and root freely in spring. Of greenhouse plants, the camellia, oleander, and similar plants, may be given as examples. These should be allowed to form their callosity in a low temperature, which should be increased as the roots begin to appear.

*Cuttings of young wood.*—The majority of hardy soft-wooded flowering plants will readily root by this means. Pinks, carnations, double wall-flowers, and most double-flowering herbaceous plants, penstemons, salvias, verbenas, dwarf lobelias, snap-dragon, lychnis, mimulus, &c., may be given as examples. And of soft-wooded greenhouse plants, pelargoniums, fuchsias, cuphia, heliotropium, calceolaria, selago, tropæolum, maurandia, &c. These should be cut immediately under an eye or bud, as shown in fig. 122, their lower leaves removed so far only as the cutting is to be planted in the soil or sand, the leaves above that being left entire. They should also be planted as soon after they are removed from the parent plant as possible, to prevent their suffering from unnecessary evaporation. They should be placed in pots well-drained, and half-filled with the soil congenial to the species; over that should be laid a covering of pure white sand, in which there are few or no traces of iron or earthy matter, of a thickness somewhat more than

the depth to which the cutting is to be set, say from one-half to an inch

Fig. 122.

CUTTING OF PELARGONIUM.

cutting is to be set, say from one-half to an inch in depth. It is of much importance that the cuttings be planted before the leaves flag, and it is of equal consequence that they be arranged as near to the edge of the pot as possible; those so placed will root sooner than such as are set nearer the centre. In striking soft-wooded plants, no suspension to their energies should be allowed to take place if possible; hence their leaves should not be permitted to flag, the operation should be carried on in the shade; and when planted they should be gently watered, and the pots plunged in a slightly-heated hot-bed, and air excluded by covering with bell or hand glasses, if the convenience of a properly-constructed propagating pit is not at command. Shading from bright sun, keeping the atmosphere damp around them, and maintaining a uniform mild heat, are the conditions most favourable for their speedily striking root. Care must, however, be taken that they suffer not from damp, and that air be admitted to them gradually, and increased as the process of rooting advances. This requires not daily, but almost hourly attention. Soft-wooded stove-plants require a bottom temperature of from 70° to 80°. Greenhouse soft-wooded plants, on the other hand, require it in a less degree, say from 50° to 60°, particularly until the callus is formed, after which, and when the roots are growing, it may be increased 10° more. Some of these, however, should have no extra bottom-heat beyond that of the temperature of the house or pit they are placed in until their callosity is formed, after which an increase as above will stimulate both the roots and young shoots. No leaves should be cut off or reduced in size unless they are numerous and large, and even this can only be sanctioned to the extent of preventing a greater degree of evaporation taking place in them than can be supplied by the cutting or the humidity which surrounds it; and shading should only be resorted to with a view to secure the same end. Too close an atmosphere, accompanied with the necessary moisture around soft-wooded cuttings, tends greatly to destroy them, by causing them to damp off; and this is more to be guarded against when they are closely covered with bell or hand glasses than when grown in a properly-constructed close pit, where the glass roof can be slightly obscured or covered with thin canvass, thus modifying both the amount of light and air. All soft-wooded plants are readily increased by cuttings, if the above conditions be complied with. As soon as the cuttings begin to grow, more air and light should be admitted to them; and such as begin to push up weakly shoots should be topped, and, when fairly rooted,

transplanted from sand into small pots in their proper soil.

The hard-wooded plants that strike best from young shoots or tops are *Erica*, *Epacris*, Chinese azaleas, *Perium*, *Chironia*, the majority of Australian plants, *Cytisus*, **Begonia*, *Boronia*, *Burchellia*, *Calothamnus*, *Calycanthus*, *Ceanothus*, *Chamæcistus*, *Cistus*, *Chimonanthus*, *Helichrysum*, *Astelma*, **citron*, *clethra*, *clianthus*, *colletia*, **combretum*, *coronilla*, *corræa*, *cotoneaster*, **croton*, *daphne*, *deutzia*, *diosma*, *adenandria*, *dracophyllum*, **echites*, *Edwardsia*, *elaegmus*, *empetrum*, *enkianthus*, *ephedra*, *escallonia*, *fontanesia*, **Franciscea*, **gardenia*, *gardoquia*, *gnidia*, *gravellia*, *Hudsonia*, *hyssopus*, *Ilex*, *Illium*, **Ixora*, **Jatropha*, *Lambertia*, *Laurus*, *Lechenaultia*, *Ledum*, *Luculia*, *Medicago*, *Metrosideros*, **Murraya*, *Myrtus*, *Phyllica*, *Pimelea*, *Plumbago*, *Polygala*, *Psoralea*, **Quisqualis*, *Solea*, *Weigelia*, &c.

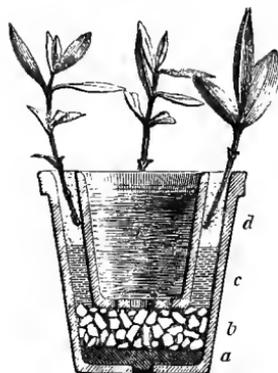

These, with the exception of those marked *, will strike, if placed in a moderate bottom-heat, say of 55° to 60°, until the callus is formed, when it may be increased to 65° or 70°. Those marked * will require from the first a bottom temperature of from 70° to 85°, accompanied by the conditions stated above.

Many plants, however, are difficult to strike by cuttings by any of these means; other modes are therefore resorted to, as in the case of the orange and lemon, the cuttings of which should be cut off under a bud, and their base made to rest on the bottom of the pot, without the intervention of any soil whatever—"the object of which seems," as observed by Dr Lindley, "to be to place the absorbent or root end of the cutting in a situation where, while it is completely drained of water, it may, nevertheless, be in the vicinity of a never-failing supply of aqueous vapour. If it were surrounded by earth, water would readily collect about it in a condensed state, and the vessels being all open in consequence of being cut through, would rise at once into the interior; but the application of the root end immediately to the earthen bottom of the pot, with which it is so cut as to be nearly parallel, necessarily prevents any such accumulation and introduction of water, unless over-watering is allowed." In following out this principle, the intelligent reader will naturally discover that shallow pots or pans are better for the purpose than those that are of the usual depth, unless they be only half filled with soil, so that the base of the cutting may touch the bottom without being of too great a length, which would disfigure, in many cases, the future plant. By only half-filling the pot, the sides above the sand or soil afford a partial shade; and where bell-glasses are not at hand, a piece of glass may be laid over the mouth of the pot as a very good substitute.

Mr Alexander Forsyth, one of our most intelligent gardeners, many years ago published in "The Gardeners' Magazine" (vol. ii. p. 564) an improvement on this mode. Fig. 123 will show his principle. A 48-sized pot was rendered water-tight at the bottom, by pressing a handful of clay, *a*, over the drainage holes, above which he placed broken crocks, *b*,

so as to raise the bottom of a small 60-sized pot placed within the other, so that the tops of both should be level. The

Fig. 123.

STRIKING CUTTINGS.

spaces between the inner and outer pots he filled up with soil, *c*, proper for the plant to root in, and above this white sand, *d*, placing the cuttings so that their bases should rest against the sides of the inner pot—which latter is filled with water, *e*, which, passing through the sides of the pot, reaches the cuttings. Others have, to effect the same end, placed a flat piece of crock under the base of each cutting, at such a depth in the soil that the cutting shall rest upon it; and others insert a smaller pot, turned bottom upwards, within a larger one, and insert the cuttings round the sides of the inverted pot. This is a good plan where bottom heat is applied, as it ascends within the inverted pot, and reaches the roots better than if it had to ascend through the soil.

Cuttings of plants that are slow in forming a callus are sometimes half severed from the parent plant, and allowed to remain so until the wound be healed and the callosity begin to form, a circumstance which leads to the belief that air is a necessary agent in its formation. Plants containing a large pith are often difficult to strike, and those with hollow stems are equally so: in such cases the joint or node should invariably be cut through; and in this, as in all other cases, the cut should be made with a clean sharp knife. Regarding the choice of cuttings, where strong and upright plants are required, the tops of the leading shoots, or the strongest of the side ones nearest to them, should be chosen; and where less robust and bushy plants are aimed at, then the more slender side-shoots, and those nearest the bottom of the plant, should be taken. These latter shoots, if taken off with what is technically called a heel—that is, a small portion of the older branch at the junction between the two—will strike more readily, as the portion of heel removed is in general well supplied with very minute incipient buds.

The best time for taking off cuttings of greenhouse and stove plants is in spring, or early in summer, that the young plants may be established before next winter. There are, however, circumstances which set this rule aside, and in such cases the process must be carried on at other seasons. Many hard-wooded plants require to be slightly excited into growth early in spring, to cause them to push out shoots fit for the purpose; by this means many heaths and

other plants which do not strike readily, or take a long time to root, are pushed on, so as to be established before the close of the growing season.

*Bottom heat.*—The importance of bottom heat, accompanied with sufficient light and moisture, is thus spoken of by Professor Balfour, in "Class Book of Botany," p. 658: "In causing cuttings to strike, we require a somewhat higher temperature than that of the climate in which they naturally grow. A willow-cutting stuck in the open ground will strike root; but it does so much faster, and more vigorously, when placed in a hot-bed. A white-thorn cutting in the open ground will not root at all; in a warm propagating-house it will do so readily. It is not the temperature of the atmosphere, but the temperature of the soil that requires to be raised. We must first obtain roots, and then leaves will follow. The cellular tissue of roots is first produced by a local process, and the production of this tissue is kept up by the heat of the soil: hence the necessity for bottom heat, in order to secure good roots in the first instance; and without them there will be no vigorous leaf-buds." This has reference more directly to cuttings of soft-wooded plants, which, immediately after being inserted in the soil or sand, begin to form roots, often in the course of a few days. Others require longer time; and some require months, before the stimulating effects of heat should be applied. On the advantage of bottom heat applied at the proper time, Dr Lindley remarks, in "Theory of Horticulture," p. 213: "This is for the purpose of giving them a stimulus at exactly that time when they are most ready to receive it. Had they been forced at first in bottom heat, the stimulus would have been applied to cuttings whose excitability had not been renovated, and the consequence would have been a development of the powers of growth so languid that they probably would not have survived the coming winter; but the stimulus being withheld till the cuttings are quite ready for growth, it tells with the utmost possible effect."

Many plants, like the oleander, will strike roots if their ends be placed in water, and, when sufficiently rooted, may be planted in ordinary soil. Others, such as pelargoniums and verbenas, will root readily if planted in damp sphagnum; and many shrubs, such as the rose, will root readily in half-decayed flax-dressers' refuse. Most plants will root, if set in the soil natural to them; but the universal medium in which all valuable plants, and such also as are difficult to root, succeed best in, is clean silver sand laid over the soil in which the plant delights, so that when the roots pass through the sand they find their natural supply of food awaiting them. Many plants, although they will root freely in sand, refuse to grow in it, and in such cases the cuttings should be removed from it as soon as their roots are formed, and potted in soil congenial to them.

Cuttings of heaths, and similar hard-wooded plants, may be safely sent to a great distance, if placed loosely in a tin case, with from a teaspoonful to a table-spoonful of water, according

to the size of the case, and that hermetically closed. We have known them so sent from Edinburgh to Vienna; and further, Dr Falconer, in reference to deciduous cuttings, directs that they be cut early in November, choosing oldish and firm wood, with the greatest number of buds; cover their ends with wax, and roll them up separately in cotton; make them up in bundles of from six to ten cuttings in each, and envelop them again in cotton covered with paper, and finish with a wrapper of stout silk or cloth, coated on the inside with India-rubber in the liquid or adhesive state, so that the side and end folds may adhere together for the exclusion of both air and wet. In this way Professor Balfour states, in "Class Book of Botany," p. 658, "slips have been sent to Saharanpore via Bombay (a distance of 7000 miles from Falmouth), in a state fit for planting when transmitted, in less than two months; and cuttings to be grafted will continue good double that period. Sometimes ringing is had recourse to, in the case of cuttings of plants which are difficult to strike. The interruption of the sap caused by this process has the effect of forming a callosity, which, if inserted in the ground after being separated from the plant, sends out roots freely.

*Piping* is a species of propagation differing not in principle from striking by cuttings. It is applied to pinks, carnations, and similar herbaceous plants having jointed or tubular stems. Pippings should be put in as early as they can be got fit for the purpose, that the plants may become strong before winter, which in England is about the end of May or beginning of June. They are taken from the young shoots of the current year's growth. The lower leaves, in the case of pinks, are stripped off to within two or three joints of the top of the cutting. The lower part is cut off, close under a joint, with a clean and sharp knife. "When prepared, throw them into a pan of water, for from five to seven minutes, to stiffen. The piping-bed being ready, press them into the soil about three quarters of an inch, and the same distance apart: give a good sprinkling of water, and as soon as the foliage is dry put the glasses over them. In about three weeks they will have rooted: at this period the glasses may be removed by degrees, first lifting them half an inch on one side for a day or two, and then all around; about the fourth day they may be taken off. Pinks will root as freely under a north wall as anywhere, and require less attention in shading when in such a situation. Prepare a layer of spit dung, let it be put together thoroughly wet, and beat down with a spade to a level surface: if 8 inches deep, it will be quite sufficient to keep the worms from disturbing the young plants. On this must be placed the compost for the plants to root in, 3 inches deep. This should also be in a moist state, but not wet, and be moderately pressed to a smooth surface. The compost for the purpose must be of a sandy quality—leaf-mould or decayed vegetable mould, and silver sand sifted fine, equal parts of each. In the absence of the above, any sweet and sandy soil, proportioned as above, will answer; but we give the preference to leaf-mould from its cool

and retentive nature."—Mr NEVILLE in BECK'S *Florist*.

Fig. 124.

PIPPINGS OF CARNATIONS.

of shortening the leaves of their pipings, and prepare them as shown, fig. 124, a; b exhibits the mutilated piping of bygone times.

*Propagation by cuttings of the root.*—Many plants may be multiplied by cuttings of the roots, instead of the more usual way of using portions of the branches or young shoots. Mr Knight has shown that the energies of a variety, artificially produced (a hybrid), exist longer in the system of the root than in that of the stem; so that it is more expedient to employ the roots of old varieties of fruit trees for cuttings than to use the stems. Many rare trees, shrubs, and plants are propagated by this means, and excellent thorn-hedges are formed by planting cuttings of the roots—that is, pieces of them about a foot in length; and even chips, having some portion of the bark on them, of the poplar, if planted, will produce trees. In both cases adventitious buds exist, and these, when called into action, form the future plants. Horseradish, sea-kale, &c., if their roots be cut into pieces of only a few inches in length, and laid horizontally in the soil and slightly covered, will form roots at the one end and leaves at the other. The Moutan pæony is most successfully multiplied by cuttings of the roots. The common plum-trees and *Pyrus japonica* are readily propagated in a similar manner, plums having an extraordinary power of forming buds on their roots. That beautiful and not long introduced plant, *Anemone japonica*, has this property in an eminent degree all over the surface of its roots, so that they may be chopped into very small pieces, yet each of these is capable of forming a new plant. And amongst the equally interesting family of *Oenothera* the two species (*O. macrocarpa* and *O. cespitosa*) are scarcely, excepting by seed, capable of being otherwise multiplied. *Acacia pubescens* amongst greenhouse plants, and some of the *Ardisias*, *Clerodendrons*, *Draacenas*, &c., amongst stove plants, are only by this means increased with certainty.

*Cuttings of the flower-stems* are found to be the best mode of propagating the double-flowering varieties of the scarlet lychnis, double rockets, and many similar border-plants; these, if cut

This may be considered the English practice. In the north, where the growth is later, slight bottom-heat is often required to make up by slight excitement what we want in warmth of climate and time to secure strong plants before the season of growth terminates. The best florists have long abandoned the absurd practice

into lengths before flowering, and placed under a hand-glass in a shaded border, root freely.

*Cuttings of leaves.*—Some idea of this mode of reproduction was entertained about the beginning of the last century, as in a work in Dutch by Agricola we find copperplate illustrations showing whole fields covered with orange leaves represented as growing into trees. Although this is sufficiently absurd, still a knowledge of the fact that some plants will strike roots from their leaves must have been possessed. The leaves of the orange, aucuba, and the fig, being furnished with adventitious buds, will multiply in this manner, as will also most of the genera *Achimenes*, *Gloxinia*, *Gesnera*, and many other plants of like habit. Some of the *Begonias*, and many succulents, do the same; and the old and much

PROPAGATION BY LEAF.

at its base a bud which is constantly axillary to itself."

neglected *Bryophyllum* produces abundance of young plants along the margins of the leaves. The process is as simple as the result is certain, and all that is required is to lay the leaves flat down on the surface of silver sand, keeping them in their place by pegging them down; or, better, laying a small stone upon them, placing them in heat, with a due amount of moisture and shade, as in other cuttings: from the veins *a* and crenate notches *b* around their edges, roots will speedily issue, as shown in fig. 125; and when formed, the leaf, if it has not rotted away, may be torn up into pieces. Sometimes the foot-stalk of the leaf is inserted in the sand as if it were a cutting proper, in which case an excessive development of cellular tissue takes place at the base; a callus is formed, from which roots proceed, fig. 126, and afterwards a leaf-bud, which forms the future plant. "It is not surprising," Dr Lindley remarks, "that leaves should possess this quality, when we remember that every leaf does the same thing naturally while attached to the plant that bears it; that is to say, forms

Besides the plants we have named above as capable of propagating themselves by this means, the following are given as examples by Professor Balfour, in "Class Book of Botany:" "Some leaves naturally produce buds on their surface, as may be observed in *Malaxis*, *Aspidium bulbiferum*, and *Nymphaea micrantha*. Other leaves, when placed in particular circumstances, give rise to leaf-buds at their margin. Thus the leaves of *Bryophyllum calycinum*, when placed on the surface of damp soil, exhibit little roots all round their edge. The leaves of *Dionaea muscipula* can also be made to produce buds, and so can those species of *Gesnera*, *Gloxinia*, and *Achimenes*. Occasionally leaves take root and form plants, as was observed by Knight in *Mentha piperita*. Buds are formed accidentally on the leaves of *Drosera*, *Portulaca*, *Cardamine pratensis*, and *Nepeta glechoma*. They are also formed on fleshy detached leaves, as on those of different species of *Crassula*, *Aloe*, on the bulb scales of *Eucomis regia*, *Lilium candidum*, *Hyacinth* and *Squill*, and on the leaves of *Ornithogalum thyrsoides*. The leathery leaves of *Ficus elastica*, *Hoya carnosae*, and of species of *Citrus*, *Aucuba*, and *Theophrasta*, are occasionally bulb-bearing."

Bell-glasses and hand-glasses are placed over newly-planted cuttings, with a view to preserve a uniform degree of humidity in the atmosphere by which they are surrounded, and to prevent, by the almost exclusion of air, that draught on the energies of the foliage which would take place were they not protected from its action. An excess of heat, cold, air, water, and even light, are alike injurious to tender cuttings; and, therefore, to guard against these extremes such coverings have been adopted.

## § 6.—PROPAGATION BY LAYERS.

Layering is one of the simplest, and probably one of the most primitive of all modes of propagation. It consists generally in bending down the branches of shrubs or trees which are produced nearest the ground, and sufficiently flexible for the purpose, so that a portion of their length near to the middle may be covered with earth, and so bent that the point of the branch may be placed in a perpendicular direction. The object of layering is to multiply the tree or plant without alteration in its character. The result, however, often is that a tree originated by layering does not always assume the robust and upright character of its parent, but assumes that of a rooted branch, as is often exemplified in the case of coniferous trees. This may, however, be corrected by cutting over the layer, after it is fairly rooted, near to the ground, where some latent bud may spring, and so send up a proper leader. It is also employed in the case of plants which are difficult to graft or bud, and which do not strike freely by cuttings, or produce seeds in this country. Herbaceous plants, such as the carnation, strike root readily from layers, and make as good plants as if propagated by any other means. Hardy shrubs with long trailing branches, like

the clematis, honeysuckle, Wistaria, &c., propagate readily by this means: the branches being trained along the surface of the ground, strike root at every eye or joint, but are made to do so usually at every alternate joint; and some of them, like the bramble, will emit roots from the growing point, if inserted in the soil to the depth of an inch; and the same mode has been practised with the common gooseberry. Roses, for the most part, are multiplied by layering, the operation being performed during spring or autumn, and sometimes at both seasons in the same year. The supply of plum and paradise stocks for grafting or budding fruit-trees on is procured by a species of layering, consisting merely in spreading out the branches on the surface of the ground, pegging them down early in spring, and covering them entirely, excepting the very points, with soil to the depth of half an inch. During summer, every bud sends up a shoot and produces roots at its base, forming by autumn a perfect plant, which is then cut off and transferred to nursery lines. The vine is often, in nurseries, propagated by bending down the shoots, and laying them in pots plunged in the ground; but this is by no means a process to be recommended, as vine-plants so produced are seldom well rooted.—(Vide art. VINE.) Many rare plants, difficult to increase otherwise, are laid in pots suspended so as to admit of their being either bent within the circumference of the pot, or introduced through the drainage-hole in its bottom; and sometimes the Chinese practice is followed, of forming balls of earth, covered with moss, around the branch, and supporting it there until roots are formed in the mass.

*The season for performing the operation extends nearly over the whole year.* Hardy trees and shrubs are usually operated upon in spring, before the ascent of the sap, or delayed until the sap is pretty well up, towards the middle of summer. In nurseries where propagation is carried on to a large extent, very many of the hardy trees and shrubs are layered during autumn and winter. With plants in the artificial atmosphere of a hot-house the case is different, and hence the operation may be performed at such times as the plant is found to be in a fit condition, irrespective of the above seasons. The best condition for the shoot to be in, is when that part of it where the sap is to be interrupted, whether by tonguing, ringing, notching, twisting, slitting, piercing, or bending, is somewhat mature, or what is called half-ripened. The shoots most proper to select are those in a healthy vigorous state of growth; and the most improper, such as are stunted, diseased, or imperfectly formed. Old wood will root in time, but neither so soon nor with the same certainty as half-ripened wood, because the flow of the sap is more sluggish in the former than in the latter.

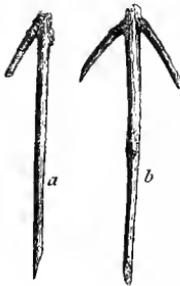

*The operation of layering* is thus performed in general practice: The ground around the stool or parent plant, presuming it to be growing in the open ground, is loosened carefully, and if dry, moderately watered; the shoots intended to be laid are then selected individually. If, as

in the case of the rose or similar shrubs, only each shoot is to become a new plant, an incision is made on the under side of the shoot, and a few inches from its base; the top of the shoot is gently bent upwards, both with a view to give the future plant an upright direction in growth, and also to keep open the incision, particularly when tongued. In this position it is let into a slit formed in the soil, the part where the incision is made being the point of connection between the descending portion of the layer (which is to be removed after rooting has taken place), and the upright portion of the layer which is to constitute the future plant; the earth is then firmed about the shoot, which so far completes the operation. In layering, a great error is often committed by inserting the part to be rooted too deeply in the ground, and this is often done to save the trouble of pegging them down with a hooked stick. From 3 to 6 inches is the proper depth for layers of trees or shrubs; but even this must be regulated by their size and age. The shoots of the previous season's growth are the most proper for this purpose, although older branches, particularly of soft-wooded trees and shrubs, in extreme cases, may be used: but these require a longer time to root, and often have to be examined; and when indications of the formation of granulous matter do not appear, fresh incisions should be made to induce this state. Or the suggestion thrown out by Mr Knight may be followed of taking up the layer entirely, and removing a ring of its bark below where the former incision was made, so as completely to prevent the descent of the sap, and thereby force the shoot to employ it in the formation of roots. The part of the layer at which the incision is to be made, should be immediately under a bud or joint, which is the point most favourable for the emission of roots. The depth to which the incision should be made depends much on the nature of the plant, but in ordinary cases it should only penetrate into the alburnum, and not through it, as in the latter case the ascent of the sap would be arrested, and the buds and leaves above it prevented from performing their proper functions; whereas, in the former case, the effect desired will be accomplished, which is to form an impediment to the descending sap, causing it to exude at the wound, and form that granulous matter which is the certain indication of the first formation of roots. There are various means of causing this interruption to the descending sap—namely, ringing, or removing a ring of bark, wholly or in part, from the layer; twisting it by bending it at a very acute angle; cutting a notch out of it; forming a slit or tongue, kept open by placing in it a small piece of chip or stone; twisting a piece of wire tightly round it; boring a hole with a broad awl or gimblet, or driving a nail or peg through it. Several of these practices are sufficiently barbarous as well as uncalled for: ringing in particular cases, and notching, tonguing, and twisting in ordinary ones, are all that is necessary; and often a thin slice of bark paired off the side of the layer is found sufficient. The fact of the sap ascending chiefly through the

albumum to the leaves and buds, and descending in an elaborated form by the inner bark, forming in its downward progress a new layer of albumum, shows sufficiently that even ringing does not interrupt the rising of the sap in spring, so long as the albumum is not cut through; yet its descent is interrupted in consequence of the incision made during the operation of ringing, and which, although it merely cuts into the albumum, in no way affects the inner bark. A granulous callosity is formed at the point of interruption, from which roots will in due time protrude. In the case of some trees, if the incision in the layer does not extend half-way through, no granulous matter will be formed the first year; but, on the other hand, if the incision is made much deeper than half the thickness of the layer, then the ascent of the sap is interrupted, and the shoot naturally dies.

The manipulations of this mode of propagation are exceedingly simple; the following will explain the routine. In ordinary cases of nursery layering, the plant to be propagated is called the stool, and hence all nurserymen have their stool ground, in which is planted every kind of tree or shrub to be thus increased. Stools are cultivated only for the production of shoots proper for layering, hence they are cut close down to facilitate the operation. The stool occupies the centre, the young healthy wood is reserved, and the slender and unhealthy is cut out. The ground around being loosened up, shoot after shoot is gently drawn down from the stool; a notch, tongue, or other incision is made on its under side, and from 6 to 10 inches

Fig. 127.

PEGS FOR LAYERING.

from its base the earth is opened, and the layer is fitted into the soil, of a depth according to its nature and strength. It is then secured in the desired position by a hooked peg, fig. 127, *a* single, *b* double, or by a shoot of flexible nature, such as willow, which is twisted at the middle, and the two ends thrust into the ground, one on each side of the layer; the soil is laid over it, the point of the shoot cut off, leaving one or two eyes above the ground surface. The incision for the

most part consists in simply entering the knife below a bud, and cutting to such a depth as has already been noticed, and drawing the knife upwards, leaving what is in common phraseology called a tongue; sometimes a simple notch is cut out: in the former case, a bit of tile, thin stone, or chip of wood, is inserted to keep the tongue open or the wound from collapsing. Some plants will root freely without any incision being made, others if only a small portion of the bark be pared off; some if they are slightly twisted or fractured, while others will not, unless a ring of bark be taken off or tightly bound round with a piece of wire. The effects of all these are the same—namely, the obstruction offered to the descending sap, and the consequent formation

of granulous matter, and the after protrusion of roots. In the case of trees which are too strong or too brittle to bend down, so that their side branches may be laid in the ground, the process of plashing them—or of elevating the soil in pots, boxes, or raised banks—must be had recourse to. In the former case the branch may be plashed—that is, cut in its under side—causing the direction of the fracture to run towards the main stem, cutting and proceeding until the branch will readily bend as low as required, taking care, however, that a sufficient portion of the bark remains unbroken on the upper side. The side branches may then be laid in the usual manner.

The time required for layers becoming sufficiently rooted to be fit for separation from the stool, depends on a variety of circumstances. Some trees and a few shrubs require two years; roses, and the majority of similar shrubs, if their present year's wood be operated upon when about half ripened, will be fit for removal the same autumn; if laid in spring or the winter preceding, they will be ready about the same time; while herbaceous and soft-wooded plants will produce their roots in a few days or weeks: and the same will occur in the case of many plants under artificial excitement.

*Layering herbaceous plants* is had recourse to in the case of rare or valuable plants, as being attended with much less risk of losing the plant than if the more ordinary process of making cuttings were adopted: it is also had recourse to with a view of getting stronger plants in a less space of time. The process is commenced when the shoots are of sufficient lengths and have attained some degree of consistency, which state usually occurs about the time the

Fig. 128.

LAYERS.

plant is coming into flower. The annexed cut, fig. 128, shows the principle in the case of a double sweet-william, *dianthus barbatus*, flo. pleno. The lower leaves of the best-formed shoots being cut off, a thin budding-knife is inserted below a joint or bud, and is passed half through the branch, and continued about three-quarters of an inch upwards, the bending of which upwards keeps the cut open, while the shoot is pegged down, and covered with soil, somewhat sandier than that in which the plants are growing. The form of the peg used in laying is as represented in fig. 127 *a*, *b*; but often, and perhaps more conveniently, a small twig of willow may be used, cut to the length of 6 or 8 inches, and bent over, both ends of which are thrust into the ground, and keep the layer in its proper place. And in some extreme cases, where a shoot is sent from a distance, or accidentally separated

from the original plant, the root end is placed in a phial of water, and the top end laid in a pot. The intention of the end being kept in the phial of water, is to supply it with moisture while the rooting is taking place.

*Propagating by cuttings of single eyes or buds.*—Next to the seed, the eye or bud is the part of a plant by which its propagation is best effected. This has already been shown in the cases of budding, grafting, layering, and striking by cuttings, in neither of which cases can roots be formed or growth be effected without the presence of a bud. Buds thus containing within themselves the elements necessary for the production of a new plant are taken advantage of by cultivators, although not to the extent in practice that might be, seeing that, theoretically speaking, almost all plants are capable of being so increased. The potato, Jerusalem artichoke, &c., ever since their introduction, have been propagated by eyes; the vine, since the time of Speechley, by the same means.—(Vide art. VINE.) Many exotics, both woody and herbaceous, as the bignonia, hollyhock, &c., are readily multiplied by single eyes. In deciduous plants, like the vine and bignonia, it is only necessary that the eye should be dormant, and that a portion of the wood on which it is produced be taken with it. This portion of wood is in general not more than an inch in length; and often when buds are placed opposite to each other, this piece of wood is split through the middle, each eye forming a plant. There is no obvious reason why we should be so sparing of this piece of wood, seeing the larger it is the more organisable matter it must contain, and consequently support the bud with a larger amount of nutriment, until it forms roots for its own support. It therefore follows that buds having 6 or 7 inches of the wood on which they are produced, instead of one inch, left attached to them, and covered with soil, must afford a proportionably greater supply of strength to the nascent branch. The late Mr Knight appears to have been of this opinion, and in the 2d vol. of the "Hort. Soc. Trans." offers the following explanation: "Every leaf-bud is well known to be capable of extending itself into a branch, and of becoming the stem of a future tree; but it does not contain, nor is it at all able to prepare and assimilate, the organisable matter required for its extension and development. This must be derived from a different source—the albuminous substance of the tree, which appears the reservoir in all this tribe of plants in which such matter is deposited. I found a very few grains of albuminum to be sufficient to support a bud of the vine, and to occasion the formation of minute leaves and roots; but the early growth of such plants was extremely slender and feeble, as if they had sprung from small seeds; and the buds of the same plant, wholly detached from the albuminum, were incapable of retaining life. The quantity of albuminum being increased, the growth of the buds increased in the same proportion; and when cuttings of a foot long, and composed chiefly of two-year-old wood, were employed, the first growth of the buds was nearly as strong as it would have been if the cuttings had not

been detached from the tree. The quantity of albuminum in every young and thriving tree, exclusive of the palm tribe, is proportionate to the number of its buds; and if the number of these were, in any instance, ascertained and compared with the quantity of albuminous matter in the branches, stem, and roots, it would be found that nature has always formed a reservoir sufficiently extensive to supply every bud. But those of a cutting, under the most favourable circumstances, must derive their nutriment from a more limited and precarious source, and it is therefore expedient that the gardener should, in the first instance, make the most ample provision conveniently within his power for their maintenance, and that he should subsequently attend very closely to the economical expenditure of such provision." This explanation applies also to cuttings set in the usual manner, but in such cases a considerable portion of the cutting is exposed to the air, and subject to lose much more of its organisable matter than when laid flat and covered with soil in the way that a cutting of a single eye cut to the length of an inch would be. We have invariably found, in propagating by this means, that when 3 or 4 inches on each side of the bud or eye have been retained, and when their ends have been covered with sealing-wax, and the whole cutting, except the eye, covered with soil, the young shoots produced have been much stronger than when the cutting has been planted erect, or when it has been divested of its wood, as done in general when single eyes are used. Plants having large buds strike readier by eyes than those having small buds—no doubt for the reason conjectured by Lindley, "that such eyes are not sufficiently excitable, and that consequently they decay before their vital energies are roused; and, in addition, they do not contain within themselves a sufficient quantity of organisable matter upon which to exist until new roots are formed."

Knight's explanation, and the sound reason last given, perhaps led to the process of propagating the vine by what has been called the coiling system already referred to, for which see fully art. VINE.

The rarer and better kinds of hollyhocks and many similar plants can only be increased, with a certainty of continuing the already improved varieties, by an extension of themselves by cuttings, and this is usually done by cutting down the principal stem so soon as it shows its merits on flowering. The young shoots which, after this treatment, spring from the crown, are usually selected for cuttings; and as they are not very profusely produced, the progress of increase is necessarily slow. A more expeditious mode of increase will be found by dividing the weaker shoots which rise round the main one, after they have attained the length of 18 inches or 2 feet, into cuttings of one bud each, much in the way vines are propagated. These bud-cuttings, when planted in light rich soil, will each produce a plant under ordinary good management. The main stem may also be used if cut in lengths of 2 or 3 inches, dividing the stem longitudinally, taking care not to injure the

buds, and placing the cuttings thus formed slightly under the soil, but not so deep as to cover the top of the bud; granulation will take place round the edges of the bark, and roots will emit themselves freely. When these have become sufficiently formed, they must be taken up and planted in a prepared bed, to gain sufficient strength for planting out permanently. By this process, from fifty to a hundred plants may be produced from one. Holyhocks raised from seed, however carefully saved, can never be depended upon for perpetuating the identical variety.

The importance of buds in the propagation of plants, although well known to botanists, has hitherto been comparatively little attended to by propagators in general. Their universality is much greater than is usually thought; for as has been stated by Professor Balfour, in "Class Book of Botany," the higher classes of plants may be considered as consisting of numerous buds united on a common axis. These possess a certain amount of independent vitality, and they may be separated from the parent stem in such a way as to give origin to new individuals. In some instances buds are produced, which

are detached spontaneously at a certain period of a plant's life, as instanced in stem buds of *Lilium bulbiferum*, *L. tigrinum*, *Ixia bulbifera*, &c. "The cloves formed in the axles of the scales of bulbs are gemmæ, or buds which can be detached so as to form new plants. Such is also the case with the corms of Colchicum. In these instances buds are developed in the usual way in the axles of leaves or scales—that is to say, at the points where they join the stem." Besides the true or visible buds, there are embryo buds contained in the bark of many, nay, probably of most trees. Of these are the excrescences called *uovoli*, found in the bark of old olive-trees, and, according to Signor Manetti, used by the Italian gardeners for propagating that tree. These are supposed by Professor Lindley to have been "adventitious buds developed in the bark, and by the pressure of the surrounding parts forced into those tortuous woody masses in the shape of which we find them." It does not appear that advantage has hitherto been taken in this country of these as a means of increasing the trees on which they are found, although there is little doubt they might be employed in cases of emergency.

## CHAPTER II.

### PLANTING.

*Planting, or rather transplanting*, which is a much more correct and definite term, is a process in horticulture regarded by many as attended with no small degree of difficulty, more especially when the subjects to be operated upon are of large size and of considerable age, we believe because the causes of success or failure are by them little understood. Others, and by far too great a number, stop not to consider causes or effects, but treat the matter as a mere mechanical operation, and consider only the most expeditious and least troublesome mode of tearing the plant from the ground, and sticking it in another situation. That want of success should follow such views is to be expected.

The earlier writers on this subject have for the most part confined their remarks to practice; more recent ones have directed their attention to the theory. Amongst these, the late Mr George Lindley considered the cause of success, in transplanting, to depend upon two circumstances—namely, the preservation of the spongioles of the roots, and the prevention of excessive evaporation. These views are also entertained by the most successful planters of the present day. The rationale of transplanting is founded on a general law in nature, by which plants are enabled to renew, within a certain time, those parts which may have been lost or injured during the process of removal, and their requiring a season of repose annually. Now, to aid them in the accomplishment of the first, is to lessen the causes of those losses and derangements, by careful lifting, transplanting, and placing them in circumstances the most favourable for their condition; the next important point is to choose that season when the plant, according to its kind, is either closing its state of excitement, in a state of repose, or just before excitement commences for another season. This extends the period of transplanting over a considerable space of time. The question, however, is, even when reduced to these limits, whether the first, second, or third states is the most proper for the operation? Each has had its advocates; and it is possible that, under certain circumstances, plants may be successfully removed during any of these stages.

Every tree, even of the same species, will not admit of being transplanted with equal success at the same time. It will, therefore, depend

much upon the discrimination of the operator, and his judgment will no doubt be regulated by the state of the roots. It will afterwards be seen that the majority of opinions are in favour of early autumn planting; but this has reference to the state of the plant as much as to the state of the season. The autumnal state—that is, the commencement of the season of repose—begins in some plants, even of the same species, sooner than in others. Small plants may always be removed with less chance of failure than large ones, because their fibres and spongioles are less liable to injury during the operation, and hence their growth suffers less interruption. Large plants, such as trees and shrubs, can never be removed without a certain amount of injury being done to their roots, and that at the points—the very parts of most importance to them, because there the spongioles are situated; and these, if once destroyed, must be reproduced before the plant can derive nourishment for its future support. Now plants such as trees and shrubs, in the open air, require that support most early in spring, before the state of foliation takes place: it follows, therefore, that plants removed during autumn must have these organs soonest produced; those during winter, next in rotation; and those late in spring, sparingly, imperfectly, if at all; and hence, in the latter case, the trees are left without support at the very time they require it most. Plants require nourishment, although in a much less degree, even when they are in what is called a state of repose, which is that season when deciduous trees are without their leaves. “When plants are in an active state of growth, a constant perspiration is taking place from their leaves, which is supplied by the absorption of the moisture in the soil by the spongioles of the roots; and when this supply through the roots is cut off by the destruction of the spongioles, the leaves wither, the plant dies, or becomes greatly injured; but there is a period in the growth of every plant in which the leaves either drop off, as in deciduous plants, or cease to be in a state of activity, as in evergreens; and it is only in this state that the operation of transplanting can be successfully undertaken with large plants. Even when trees are without leaves, perspiration is going on to a certain extent through the bark, and absorption to supply

this waste must necessarily be taking place at the same time through the spongioles; for though the functions of all plants are annually in a dormant state, yet they are never wholly inactive; and hence, even in transplanting trees without their leaves, the effects of more perspiration by the bark than the roots can supply must be guarded against."—*Sub. Hort.*

The state of the weather has very much to do with the successful removal of all plants, whether large or small. Dry, windy, and frosty weather, as well as powerful sunshine, are the most unfavourable of all. They all draw upon the vital energies of the plant, without restoring any support to it. Perspiration and evaporation go on more rapidly in such states of the weather than in any other, and this more when plants are in leaf than when they are bare, because the process is going on both by the leaves and the bark; and this is one of the principal causes why we cannot remove large trees in leaf so safely as when the leaves are off. A mild damp atmosphere is the most fitting for the operation of transplanting, and this will be greatly enhanced if genial showers of rain fall during the night. This theory has, however, to a certain extent, its opponents, but the arguments adduced by them are so weak, and so devoid of true physiological reasoning, as to be scarcely worth refuting. A sample, however, may be given, in those who assert that the Brassica tribe, for example, grow faster, when at transplanting they have been kept sufficiently long out of the soil to cause their leaves to fade. Decandolle appears to have favoured this view, and observes that it causes them to pump up moisture rapidly, in proportion to the degree in which their interior tissue has been deprived of it.

Mr Barron—no mean authority in such matters—on the other hand, believes that much of the success in transplanting large trees depends on the quantity of soil taken along with the roots—that is, that the size of the ball should be consistent with the size of the plant or tree to be removed; and that if this is attended to, trees may be removed any month in the year (as they have been at Elveston) with almost uniform success; although, he continues, spring, summer, and autumn are to be preferred to winter, for this reason—"When plants are removed in a growing state, the moisture surrounding the roots is immediately absorbed, and at once assimilated as food for the plant; the wounds where the plants have been cut across or injured speedily heal over, and fresh rootlets form, all going on in a natural process without much apparent check: but in winter, when the ground is cold, and the plant in a dormant state, the moisture which surrounds the roots, instead of being taken up by the plant, remains there in a state of inactivity, and has more or less a tendency to rot and decompose certain portions of the roots where severed. Hitherto the planting of trees has been confined to that period of the year when they have ceased growing, and are in an inactive state; and had not necessity compelled me," says Mr Barron, "to step out of the ordinary track, I might still

have been in the dark as to what can be done successfully. Had I not ventured on some bold experiments, and prosecuted my work at all seasons, but waited for the usual time of planting, in sixty years we would not have accomplished what has been done in twenty.

"Trees of large size have been moved in the middle of summer, during hot weather, with perfect safety; and I find that when an operation can be performed under favourable circumstances, the more active the state of the plant is at the time of removal, the better it will succeed." Mr Barron "has moved spruce firs in June from 30 to 40 feet in height, when the leading shoots had grown from a foot to 18 inches; and during the operation all the young shoots, and even the leader, became flaccid and drooping; but after being planted a day and well watered, all got right again; the leader became erect, and prospered as if nothing had happened. It must be understood that summer planting is only applicable to evergreens, and such as can be depended upon for *lifting with large balls of earth*. It is possible, nevertheless, to transplant deciduous trees when in leaf, but only under peculiar circumstances should it be attempted."

Transplanting is an operation in connection with fruit-tree culture, that ceases not on the first formation of a garden or orchard. Deaths are occasionally taking place, and changes of opinion as to the merits of certain kinds of fruit are constantly occurring. Where apples and pears are on healthy stocks, should the kinds not meet the approbation of the owner, these may be changed by heading them down in spring, and grafting more approved sorts on them, with much less loss of time than by replanting. This rule does not, however, apply to all the fruit trees growing in a garden, and therefore they may have to be cleared out entirely, and new plantations made in their stead. Hence transplanting is almost a daily operation in gardening. This is the case generally with strawberries, gooseberries, currants, and raspberries. The former of these require, according to the highest authorities, to be replanted once in two or three years, and some advocate the principle of replanting some varieties of them annually. Although the three next, in some very favourable localities, continue to bear well for many years, the short time required to bring them into a bearing state induces many to change their sorts, discarding such as they esteem more lightly, and replacing them with those of a higher character. Some very excellent cultivators think that the period of their useful existence is limited to a few years, and consider the fruit from plants of three or four years' growth superior in quality and quantity to those that have been in a bearing state a quarter of a century. Others make plantations every fifth or sixth year, with a view to carry out the rotation of other crops upon high cultivation principles. With these latter we perfectly agree, and this the more cordially if the ground is naturally poor, and not eminently qualified for such crops. Renewing the plantation of gooseberries has the advantage of lessening the attacks of insects, which seldom attack

them for the first two or three years after being set in a new soil—that is, one where they have not been for years cultivated. Taking up the same trees and replanting them again becomes necessary also when the roots, as in the case of the peach, the nectarine, apricot, plum, and pear, have descended into a bad subsoil, or where the branches have extended beyond their proper limits, and interfere with the neighbouring trees, and also where, from the accumulation of soil over their roots, they have got too deep to be within the power of solar influence. These and many other causes render the replanting of fruit trees so often necessary as to make this operation a subject of annual consideration.

Many good cultivators take up a portion of their fruit trees annually, shortening the strongest roots, removing a portion of the soil, and supplying its place with fresh mould, more especially towards the extremities of the roots, and placing the roots so that they may be near the surface. In most cases this is a commendable practice; and although it involves somewhat more labour than merely root-pruning the trees, the labour is well expended; because the roots are kept within proper bounds, and induced to produce numerous food-collecting fibres, instead of strong tap and extended roots, which merely act as conductors of the sap collected by the spongioles, and often, when they extend into a bad subsoil, throw into the system of the tree too great a supply (and that often of deleterious quality) of sap, inducing coarse and over-luxuriant wood, from which fruit need hardly be expected.

The season of transplanting established trees, in consequence of the still undecided state of opinions, extends in practice over a period beginning in ordinary cases in October and ending in April. Our own opinion is in favour of early autumn transplanting; and we would rather do so in October than in March, unless under very peculiar circumstances. We are aware, however, that many cases occur wherein the operation has to be carried on throughout the whole winter. Transplanting evergreens may, however, be safely done in April, early in May, and also during the latter end of August and throughout September; and they may be planted at other seasons also. Planting, when the term implies very young plants, seedlings, &c., may be safely done at various other seasons, according to their circumstances and kind. The dark months of winter may, however, be regarded as the least favourable.

Under all these circumstances, we have thought it better to treat the subject of transplanting generally, and under one head, offering first a few remarks on the preparation of the ground, as on this as much of the success depends as on either the season or manner in which the operation is performed.

*Preparing the ground for planting.*—The nature of the tree to be planted should always regulate the extent and manner of the preparation. If we except the quarters of a well-made garden, and the borders for fruit trees—and even these are not always exceptions—we will find that far too little attention has been paid to the sub-

ject. In reference to ornamental trees and shrubs, where bulk and full development of form are the objects sought, we may here observe, that care in preparing the ground for them is as essentially necessary as for the most delicate fruit-tree. But how seldom is this attended to, and how frequently is the practice followed of digging pits large or small, according to the size of the tree or plant, setting the tree in it, and filling in the soil—he it what it may—around the roots, while the ground between the plants is left wholly undisturbed. Should the tree live, and the roots extend as far as the limits of the pit, they are in general arrested there in their progress by the formidable obstruction of impervious undisturbed soil. The first consequences are, that the roots are limited to the circumscribed pasturage of the original pit, which in time becomes exhausted, and unable to afford nourishment to them. If the soil is clayey or damp, the tree may be considered as placed for half the period of its existence in a state of puddle; the roots, being prevented from extending themselves in proportion to its size, become easily overturned by wind, and, in fact, it is reduced to the condition of a tree grown in a large flower-pot, the soil within which cannot long continue to supply food to it, and hence it languishes and dies of starvation; whereas, if the soil be trenched previous to planting, these evils are avoided. The more we comminute the soil, the more nourishment will be absorbed by the roots, and the more vigorous and healthy will the plant become. “Trees, irrespective of fruit-bearing ones, far more than agricultural crops, require *depth of soil* to raise them to perfection; the effect of climate appears much less necessary in giving them their greatest magnitude. If, in transplanting, we must often increase the cold, and other circumstances adverse to trees, it becomes us the more diligently to study that the soil be rendered as *rich and deep as possible*, in order in some sort to counterbalance those disadvantages. Let it be observed, also, that an open soil, besides being favourable to the transmission of nutriment to the roots of plants, is likewise favourable to their extension, and thereby enlarges the field whence nutriment is derived. Nor are these the only benefits resulting from a friable soil; for, in addition to its being adapted to supply vegetables with food, it is always most suitable for effecting those changes in the soil itself which are equally necessary to the preparation of such food.”—*Mr Withers' letter to Sir Henry Stewart.*

There are other reasons why ground intended to be planted should be prepared both by draining and deep trenching, the principle of which is, “that the roots near the stem become in time inactive, and have little or nothing to do as preservatives of life, except by acting as conduits, while the functions of absorption go on through the spongioles, which, being at the extremities of the roots, extend wherever food and moisture are to be found. This property prevents a plant from exhausting the earth in which it grows; for, as the roots are always spreading farther and farther from the main stem, they are continually

entering new soil, the nutritious properties of which are unexhausted."—*Lindley's Introduction to Botany*, vol. ii. p. 180.

In former times, fruit-tree borders were made as deep and as rich as the means within the reach of the maker could accomplish, just on the very principles best fitted for the growth of timber, and perfectly in accordance with Mr Withers' views, and, consequently, sterility in the trees (if fruit-bearing ones) was the consequence. From this very cause also proceed late and immature growths, and that in a climate where every ray of heat from the sun is of so much importance. Modern practitioners, sensible of these errors, have adopted a different and more rational course in the formation of shallow borders, and those elevated above the general surface, or placed at the most favourable angle of inclination, so as to expose the roots to the influence of the solar rays. This elevates the temperature of the soil so as to bring it in advance of the atmosphere; or, in other words, renders it so much warmer that the roots become excited before the branches. The first effects of this is a healthy and moderate growth, and early maturity of the wood in fruit trees. The same rule should be followed in planting standard fruit-trees, because the same results are wished to be attained. In the case, however, of trees planted with a view to obtain the greatest bulk of timber within the shortest period of time, as well as of those planted for ornament, the case is widely different: for them the ground cannot be trenched or prepared too deep; and the same holds good in planting shrubberies. Single specimens, on the lawns or in the park, require equal care, the pits for which should not be less than three times the diameter of the ball, or of the extent of the roots. Many tender shrubs and trees should be planted on slightly raised mounds, so that their roots may be within the reach of solar influence, to assist in exciting them to earlier summer growth, and, consequently, enabling them to mature their wood more completely early in autumn, and hence escape the chance of being killed by frost during winter.

Preparing the ground preparatory to planting fruit trees is a subject of very great importance, whether the operation extends to the planting a new garden, or embraces only the making up deficiencies in one already existing. On the formation of fruit-tree borders we have expressed our own views as well as those of others, vol. i. pp. 27-32. The principles there laid down we consider quite sufficient to meet the generality of cases. These principles are—a dry bottom, proper breadth and depth, a congenial soil, and leaving the surface over the roots uncropped with flowers or vegetables. These identical principles apply also to orchard trees, or such as are grown without the protective shelter of walls, and in a modified degree also to individual trees planted to make good deficiencies, from whatever cause they may arise. In connection with the latter case we may here briefly remark, that the soil, for a very considerable distance around where a tree has been removed from, has become almost completely exhausted of those

elements necessary for entering into the constitution of its successor; and it may contain the seeds of disease, and abundance of the eggs of insects that have played their part in hastening the decay of the former. Surely we cannot be blind to the necessity of removing the whole, or a considerable part at the least, and supplying its place with fresh soil suitable to its kind. All plants have a strong affinity for new soil, and fruit trees in an especial degree. The soil of a long-cultivated garden, be it ever so good for the purposes of ordinary cropping, is very unfit for the sustenance of fruit trees, and this the more so according as it abounds in humus. Turfy loam from a field or common which has been long in a state of pasturage, and on which no trees of any kind have grown, is of all the most proper, and the fresher from the field it can be applied the better, and also the nearer it is taken from the surface, carrying in with it any fibrous vegetable matter that may be growing upon it. In this there is, however, some discrimination required, light friable loam being most suitable for the peach, strong clayey loam for the pear, plum, and cherry; while the apple, fig, and apricot will be quite at home in a soil intermediate between these. Where fruit-tree planting is to be carried on upon an extensive scale, the preparation of the ground should be carried on for at least during two or three months previous to planting, so that the ground may be completely drained, trenched, and exposed to the action of the weather. Where blanks only are to be filled up, and the trees to be removed are only recently cleared of their fruit, there is less time for such preparation. The spot upon which the young tree is to be set, as well as that of the border, to the extent of 4 or 5 feet from the stem, should, however, be prepared to that extent at the time of planting. This will afford sufficient scope for the roots of most trees during the first, and probably the second season; and additions to this can be made from time to time afterwards.

We are of those who believe that this yearly adding new soil to the roots of fruit trees is infinitely better than making the border, unless in the case of new gardens, all at once. A prepared space, with a radius of 4 feet, is amply sufficient for the roots of any tree for the first year after planting; that space to be yearly extended by removing a zone of 18 inches or 2 feet in breadth, and filling it up with prepared new soil. It gives the operator, at the same time, an opportunity of regulating the extension of the roots, either by curtailing them, should a too luxuriant habit be indicated, or to encourage them with generous food, should an opposite state be apparent. Under some circumstances it is more convenient also, as requiring neither an extraordinary quantity of material nor an extra amount of labour at one time. This indulgence, however, should not be allowed to extend so far as, after a year or two's compliance with the rule, to neglect it altogether. The subject of concreting, vaulting, ventilating, &c., has been already explained in vol. i. pp. 27-32; and as further notice of these improvements will be found in the forcing-garden department,

art. VINE, a detail of them is here unnecessary. The soils also for each kind of fruit tree will be described under each.

*Early autumn transplanting* has long been recognised as a leading feature in good management. It is founded on correct physiological principles, and practical experience has confirmed the soundness of it. Miller, and since his time most of the leading horticulturists of this country, have been of opinion that immediately after the fall of the leaf in autumn is the best season for the operation, in all situations where the soil is dry; but others, differing in this respect, recommend that the end of February, or indeed until the sap is beginning to rise, is to be preferred. This latter is an extreme case, and if the soil is so wet as to render this delay within even the verge of probability, this indicates a very unfit situation for trees not actual aquatics. Many excellent gardeners recommend transplanting so early in autumn that even a considerable quantity of the leaves in a mature and active state should still remain on the trees; for, they say, by the action of such leaves the injuries which the roots may sustain during the operation will be speedily repaired, new roots will be produced, and the plant will thereby become established before winter, and be in a condition to start into growth in spring, little, if at all, affected by its removal. "Early in autumn is undoubtedly the best time, considered physiologically, because then, whether the plants are with or without some of their leaves, the wounds made in their roots will begin to cicatrise, and to protrude granulous matter, and in many cases even spongioles immediately; and by the time spring arrives, the plant, if it has been taken up with most of its roots, will grow with as much vigour as if it had not been transplanted. For obvious reasons, the next best season to that immediately following the fall of the leaf is the remainder of the autumn, and the winter months during open weather. There may be local reasons why the beginning of spring may be preferable to autumn, but such reasons can never apply generally. A second argument in favour of autumn planting is the dampness of the atmosphere which prevails at that season and during winter, by which the perspiration through the bark is lessened, and the demand made on the roots to supply the waste is consequently diminished. In spring, not only is the sun more powerful, but drying winds generally prevail, which have a constant tendency to drain the young branches of their moisture. These drying winds are much more injurious to newly-transplanted evergreens than to deciduous trees, as will afterwards appear."—*Sub. Hort.* In early autumn the temperature of the soil is much higher than it is in winter or spring, on account of the solar heat absorbed by it during summer being still retained in it; and this warmth is of all things the most favourable for the production of young roots, a circumstance well known to gardeners. This of itself is, in our opinion, sufficient ground for insisting on early autumn planting. The season of transplanting, as has been already remarked, extends from the latter end of September

till the middle of February—that is, from the period when the leaves begin to change colour until the young fibres of the roots begin to form in the spring. No doubt the operation may, and often is, performed much later in spring, and also sometimes, under peculiar circumstances, even throughout the summer. In reference to the former we may remark, that trees transplanted after the middle of March have not justice done them. Many are afraid of even October planting, because the leaves are still on the trees. Let no such fears be entertained, for if trees be planted then, they will push new roots before the severe weather sets in, and will so far have established themselves before the first movement of the sap in spring. If trees are not transplanted sufficiently early in autumn to make new roots that season, it is much the same as if they had not been planted till early in spring; for new roots—the formation of which is the primary effort of every transplanted tree—will not and can not be formed during the dead months of winter, the temperature in the soil being much too low to enable them to be so. If transplanted in the end of September, or during the month of October, in ordinary soils, the solar heat absorbed during summer being still retained, will have much the same effect upon them, only in a somewhat less degree, as if they were plunged in the genial heat of a moderate hot-bed. The whole rationale of early autumn transplanting is the warmth of the soil, and the humidity then existing in the atmosphere.

Downing bears similar testimony in favour of autumn planting, and says, "that the best season for transplanting all deciduous trees is in autumn, directly after the fall of the leaf. The tree is then in a comparatively dormant state. Transplanted at this early season, whatever wounds may have been made in the roots commence healing at once, as a deposit directly takes place of granulous matter from the wound; and when the spring arrives, the tree is already somewhat established, and ready to commence its growth. Autumn planting is for this reason greatly to be preferred in all mild climates and dry soils, and even for very hardy trees like the apple, in cold latitudes, as the fixed position in the ground which trees planted then get by the autumnal and early spring rains gives them an advantage at the next season of growth over newly moved trees. Evergreens may also be planted at the same season; but with them, as with deciduous ones also, the operation should be suspended during frost, and, if possible, advantage taken of mild damp weather."

*Reasons for very early autumn transplanting.*—Winter and early spring are considered by many experienced planters to be the very worst seasons for transplanting large trees, whether evergreen or deciduous, because at that period their roots are in a comparatively inactive state, and consequently must suffer from having to remain long dormant, and unable to take hold of the new soil so as to draw nourishment from it for the support of the tree. Hence, such say that summer, when they are in their most active state, would be the proper season for this operation, provided we had such a command over

the atmosphere as to prevent too great a drain on their mutilated roots, for the supply of the leaves in the process of perspiration caused by the powerful influence of the sun's rays on their porous tissues. Shading, to prevent evaporation, and creating an artificial atmosphere around them, would do much to secure success, but the difficulties attending the accomplishment of these conditions are not easily overcome.

"It behoves us, then," says Mr Middlemas (in "Magazine of Botany"), "to look for a period when the tree is neither in a torpid state nor in its most active growth, nor when the sun's rays are so destructively powerful on trees unprepared with a sufficient supply of evaporative matter for the roots to satisfy the demands made upon them by a hot dry atmosphere; and we shall find that from the middle of August to the end of September is the best period, as providing for the circumstances of our case."

*Reasons against spring transplanting.*—We find Dr Lindley exposing the evils of spring planting both in his excellent "Theory of Horticulture," and elsewhere in his voluminous and useful writings. In a leading article in "The Gard. Chron." he observes, in directing attention to late spring planting, "If we search for solid reasons why spring planting should be adopted, we fail to discover the least resemblance to them; or if resemblances to reason do appear, they vanish the moment they are examined. The great argument in its favour is its occasional success, but this is of all reasons the most unsatisfactory. The cause of death, when trees are removed, is almost entirely that they lose the fluid contained within them faster than it can be renewed, the end being the drying up of their vessels, which is immediately followed up by a loss of vital force. If we inquire whether the circumstances to which spring-planted trees are exposed are favourable or unfavourable to this fatal loss of fluid, we find them to be the former in an enormous degree. The air is peculiarly dry in the spring, and frequently in rapid motion at the same time: all objects exposed to a current of dry air must part with their moisture rapidly, and consequently such a state of things is most unfavourable to plants which require to retain their moisture. At first their young bark is the channel through which the moisture flies off; but as soon as young leaves appear, should the trees live long enough, and the perspiring surface is thus extended, this loss goes on with far greater rapidity, and life is soon extinguished. Evergreens, which have always a very large perspiring surface, are on that account exposed to much more danger, and consequently the losses among them are much greater. That the excessive loss of fluid from the interior is the true cause of death in newly-planted trees was proved by the late Mr Knight, who surrounded their stems with damp moss, and thus preserved them. Established trees suffer nothing from the dry air of spring, because their roots are uncut, and restore the moisture as fast as it flies off from their surface. But newly-planted trees, whose roots are necessarily much mutilated, suffer, because they can-

not obtain fluid from the soil until the roots are renewed, and before that can happen they are dead; for the feebleness of the stem actually diminishes the capability of the plant to renew its roots. But it is said, if a tree is just budding when planted, it is in the most favourable state, because it will immediately make fresh root, the act of vegetation upwards being simultaneous with growth in a downward direction. There is here, however, a fallacy: it is assumed that the upward and downward vegetation will go on when a plant is transplanted, as well as if it had been left in its former place: that, however, depends on the external conditions to which it is exposed. If the surrounding air is damp, and remains so, evaporation being thus prevented for a sufficiently long time, roots will be quickly formed, and the plant will go on growing; on the other hand, if the air is dry, and exhausts the branches of their moisture, new roots cannot be formed, and the plant will die. Life in such a case is staked upon the chance of the atmosphere being in a very favourable state, and the chances are ten to one against its being so. These considerations abundantly prove the spring to be the worst of all seasons for a planter."

*Other seasons for transplanting.*—There have been many instances of successful transplanting at all seasons except midsummer; and there are many, as Downing remarks, "who, from having been once or twice successful in transplanting, when trees were nearly in leaf, avow that to be the best season, not taking into account that their success was probably entirely owing to a fortunately damp state of the atmosphere at the time, and abundant rains after the experiment was performed."

*The theory of transplanting by the preservation of the spongioles of the roots.*—This theory, although long recognised by physiologists, was first brought into general notice by Mr George Lindley, in the "Guide to the Orchard." "It is well known," he remarks, "that plants feed upon fluid contained in the soil, and that their roots are the mouths through which the food is conveyed into the body. But the absorption of fluid does not take place either by all the surfaces of their roots, nor even of their fibres, but only by the extremities of the latter, consisting of bundles of vessels surrounded by cellular tissue in a very lax spongy state, whence those extremities are called spongioles. It is only through the spongioles that absorption to any amount takes place. These spongioles are exceedingly delicate in their organisation, and a very slight degree of violence destroys them. It is scarcely possible to remove the soil from the roots without injuring them in some degree; and if transplantation is effected violently or carelessly, they are in a great measure destroyed. In proportion to the size or age of a tree is the difficulty of preserving them increased, and hence, at the same time, the difficulty of transplantation is augmented. If by any method the spongioles could be preserved unharmed, there would be no reason whatever why the largest forest trees should not be removed as easily as

the young plants in a nursery; but their preservation in such a case is impossible, and therefore the transplantation of trees of great magnitude cannot be effected. It is because of the security of the spongioles from injury when the earth is undisturbed, that plants reared in pots are transplanted with so much more success than if taken immediately from the soil. Hence, also, when earth is frozen in a huge ball around the root of a plant, transplantation is effected with the same kind of certainty. The practice of cutting the roots of large trees the year previous to removing them, is attended with success for a similar reason; wherever the roots are cut through, the new fibres which are emitted, provided the plant is in health, in short tufts, and each terminated by a spongiole, are much more easily taken out of the ground without injury than if they were longer and more scattered among the soil. When destroyed, the spongioles are often speedily replaced, provided a slight degree of growth continues to be maintained. This is one of the reasons why trees removed in October succeed better than if transplanted at any other time. The growth of a tree at that season is not quite over; and the first impulse of nature, when the tree finds itself in a new situation, is to create new mouths by which to feed when the season for growing again returns."

The importance of preserving the spongioles has been denied by Rogers, a practical writer of credit, and little regarded by planters in general; while it has been admitted by Downing, Loudon, Sir Henry Steuart, Decandolle, Dutrochet, Bonnet, Papin, Senneber, Lindley, and others. Rogers gives as a reason for disregarding the preservation of the spongioles, that they die annually as soon as they have performed their allotted functions. "In this the man of science," he remarks, "is at fault, because the practical man knows that leaves on the head of a tree are produced at the same time as the fibres are on the roots, and in many cases both FALL OFF together. The root fibres (or spongioles, if the learned must have it so) of the apple do not, indeed, all fall off, but certainly all become inert and torpid during winter. Besides, it is not altogether to the preservation of the last year's fibres that the planter looks for success; nor can the transplanted tree be much benefited by saving those organs which have already done their duty. Both the one and the other must rely on the *new* vigorous fibres which *will be produced* in the new station; and if a removed tree be planted in soil which is fine, moist, and warm enough, no fears need be entertained but that new fibres will quickly come forth to carry on the growth of the plant. In transplanting a tree, however, there is no necessity for needlessly exposing the roots to the sun and drying air; this might enfeeble the *main roots*, which would be of worse consequence to the plant than the mere loss of the spongioles—a majority of which would certainly have died, even if the tree had been allowed to stand in its former place." The Rev. Patrick Keith seems to be of nearly the same opinion; while the author of "The Domestic Gardener's Manual" thinks "that it appears unphilosophical to consider any parts of the root

to be fugacious and perishable which have been propelled by the permanent members of the tree: such are the radicles or rootlets attached to the young shoots of the past year."

This office of the spongiolets has been disputed by Link, who observes, "Many physiologists assert that the root points suck up the nutritive juices from the soil, and through the roots convey it to the plant, and hence Decandolle called them spongioles. Ohlert, an acute observer, proved that this is not at all the case, adducing in evidence of his opinion, that plants whose root points or spongiolets hang in the air continue to grow even when these points are cut off and closed over with sealing-wax. In that case, however, he admits that it is necessary the roots themselves should be in water, or in very damp earth. It is worthy of remark, that precisely at the point where the absorbing surface commences, there also the vessels with their accompanying cellular tissue commence."

As all plants draw a considerable proportion of their food from the soil, it follows as a fact doubted by no sane person, that that food, to enter into the structure of the plant, must needs be in a liquid state. No doubt, plants also derive much support from the atmosphere, which is drawn up by them in a gaseous form through the pores of the leaves as well as through the bark of the trunk and branches. These latter views are entertained by Duhamel, Marriotte, Bonnet, Papin, Priestley, Greer, Saussure, Dutrochet, Keith, &c.

The ancients had clear enough perceptions of the absorbent power of the roots; and Anacreon, in one of his little poems in honour of drinking, makes the very trees of the forest drink. Two lines in ode 19 may be thus translated:—

"The black earth drinks,  
And the trees drink it;"

meaning the moisture the earth contains.

To reach the plant, this moisture must pass through their roots; and if we examine how this is done, it will clearly enough appear that the liquid food is drawn into the roots by those innumerable little absorbent bibulous sponges (spongiolæ) with which even the finest fibre of the root is furnished. "This is the grand apparatus," says Keith, "that nature has destined to the office of the absorption of vegetable nutriment; and it is owing to the powerful absorbent property of the spongiolæ of which it consists that the scientific gardener, in the transplanting of his young trees, or the scientific and ornamental planter, in the transplanting of his trees of full growth, is so extremely careful to preserve entire even the minutest fibre and extremities of the roots."

The experiments made by Hales, many years ago, being made chiefly on the sections of roots laid bare and merely immersed in water, show only to a limited extent the absorbent power of roots, but in no way illustrate the natural action of the spongiolæ, collecting nourishment at ten thousand different points, acting simultaneously together in taking in moisture from the soil. In this respect his experiments are defective. "The absorption of juices by the

roots takes place solely by the extremity of each radicle fibril, or, which is to say the same thing, by the spongioles which terminate each of their ramifications." Decandolle had some idea of this when he remarked that young trees exhaust the earth very near their trunks, while the old ones with horizontal roots produce this exhaustion at a distance from their trunks, the more considerable in proportion as they are larger.

Modern physiologists have confirmed this opinion, in remarking the longitudinal direction of the fibres, and the thickness of the cellular envelop, which prevents the juices from reaching them laterally. Sennehier has also shown this by very conclusive experiments. "It is certain, then," he says, "that the absorption of roots only takes place by their extremities: we may here mention that it is, then, at the extremities of the roots, and not at the base of the trunk, that we ought to apply water, manures, and, in general, all the substances which we wish plants to absorb."

If preserving uninjured the spongioles, and consequently the roots of trees, even to their very extremities, be of the importance stated by the authorities above, then it would appear that, in removing a plant or tree, far less of the success depends on the compactness and size of the ball, providing every root is not contained within it, than on the preservation of the roots, which can only be preserved to a very limited extent, as all beyond the ball must of necessity be cut off. As trees increase in age and size, so do their roots diverge from their stem—no doubt in search of food, and also to enable them to maintain their natural upright position; and it is no uncommon thing for shallow-rooting trees—the *Abies* tribe, for example—to extend their roots horizontally to the extent of 40 or 50 feet, that is, giving a diameter to the field they occupy of from 80 to 100 feet. Now, according to the doctrine maintained by the advocates for the spongiollet system, the whole of the food-absorbing portions of the roots must occupy a zone forming the circumference of a circle whose diameter is equal to that given above. For Decandolle, if we mistake not, stated the theory, and almost every physiological writer of eminence since his time has confirmed his views, that the absorption of the food takes place *solely* at the extremity of each radicle fibre, by the spongiolets which terminate each of the ramifications. If these opinions be correct—and they have not been as yet controverted—it would follow that it were better to dispense with a ball altogether, and direct our whole attention to the preservation of the roots, even to their most minute points; and hence we apprehend that washing the soil entirely from the roots, tying them up in bundles, enveloping them in moss, and using every other possible means for preserving them uninjured to their full extent, will yet be considered the most likely means to insure the successful removal of very large trees.

The ball system of removal, however long sanctioned by practice, must be defective in every case in which the ball does not include within it every rootlet and spongiollet; and this

can only be in the case of very small and young plants, whose roots have not extended beyond a radius of 4 or 5 feet from the trunk; and although the rule is not without exceptions, it may be set down as pretty near the average, that the spread of the tree may be taken as nearly that of the horizontal extent of the roots. "Roots, in their lateral extension, bear usually a relation to the horizontal spreading of the branches, so as to fix the plant firmly, and to allow fluid nutritive substances to reach the spongiolets more easily."—BALFOUR in *Manual of Botany*, p. 66.

*The prevention of excessive evaporation at and after the process of transplanting.*—"Evaporation takes place in plants to an inconceivable degree in certain circumstances. In damp or wet weather this evaporation is least; in hot dry weather it is greatest. This loss has all to be supplied by the moisture introduced into the system by the spongioles; and hence, if the spongioles are destroyed, and evaporation takes place before they can be replaced, a plant must necessarily die. This is the reason why deciduous trees cannot be transplanted while in leaf: it is impossible to remove them without injuring their spongioles, and it is equally impossible to hinder the evaporation by their leaves; but if they are kept in pots, it matters not at what season their removal takes place, because, as their spongioles are then uninjured, even excessive evaporation would be made good by their action. It is well known that certain evergreens can be transplanted in almost all months; this arises from their perspiration being much less copious than in deciduous trees, wherefore the spongioles have less difficulty in supplying the loss occasioned by it; yet even evergreens cannot be removed in the hottest months of the year, because then the action of such spongioles as may be saved in the operation would not be sufficient to supply the waste by evaporation. Plants first beginning to grow in the spring, with their leaves just turning green, are in a most unfit state to remove; for, when transplanted, their roots will not have time to form a sufficient number of new spongioles to supply the loss to which the rapid perspiration by the leaves at that season will give rise."—*George Lindley*. In these views Mr Lindley is supported by Dr Hales, Guettard, Knight, and others.

Excessive evaporation may be greatly counteracted by shading, and copious applications of water thrown over the foliage and branches by a fine syringe or garden engine. We say a fine syringe, because the water so applied should be as much in the form of dew as possible, and applied night and morning until the roots have made sufficient progress to be able to supply the trees by natural means.

*Preparing the places for transplanted trees.*—Digging pits is the usual term applied to this operation, and in too many cases the term is not misapplied; for thousands of trees annually have their roots thrust into pits from which few of them ever escape. He who prepares a space sufficiently large, so that the roots may be spread out to their fullest extent in all directions,

loosening the ground below, applying, if need be, fresh soil, either in whole or in part, and taking care that the roots be not placed too deep, may be considered as one who looks upon a tree as a living subject, whose life is to be rendered long and vigorous by a good supply of food, and a soil mellow and easily penetrated by the smallest fibre. He, on the other hand, who thrusts the roots of his trees into the smallest possible hole, and supplies them with the least possible quantity of proper soil—trusting to what he seems to believe the inextinguishable powers of nature to make roots and branches under any circumstances—is starting in a very false direction.

“There is an unhappy propensity prevalent to consider a tree as destitute of the wants of plants in general, and to believe that if it is provided with sufficient soil to cover its roots—no matter what the quality may be—it cannot possibly fail to thrive; but, on the contrary, care and attention are as imperative in preparing the soil for trees, and will be followed with equally satisfactory results, as in the treatment of any other of our cultivated plants.”—STANDISH, in *Practical Hints on Planting Ornamental Trees*, p. 6.

The size of the pits for the reception of the roots depends much upon the circumstances whether the ground has been thoroughly prepared by draining, trenching, and the addition of proper soil, or whether the tree is to be planted where other trees formerly stood. In the first case, an opening twice the diameter of the roots, as we have formerly stated, when fully spread out, will be sufficient; while, in the latter case, the space should be at least double that size, having the whole of the old soil removed, and replaced with new.

*Filling in the soil at transplanting.*—This is an important matter in securing success. When the roots are spread out to their full extent on the prepared bed—which should not be the hard and impervious subsoil, but a bed of prepared compost, into which the roots may penetrate and find nourishment—the soil, which should be well pulverised, must be worked in, so that every part of the surface of the roots may be covered. Much of the success in transplanting depends on this; and more fully to accomplish it, water in moderate quantities may be given, particularly in light soils, to wash the finer particles among the roots, so that no cavities may be left about them. Watering at autumn planting is, however, of much less importance than in spring, particularly if the planting has been delayed to a late period. Where the soil can be wrought properly around the roots in a dryish state, so much the better, as the rains during winter will consolidate it, and supply the roots with the humidity they require. Although we here recommend filling in around the roots with finely-pulverised soil, we mean that only so far as to cover them. The compost beyond this can hardly be too fresh, and should contain a large portion of fibrous matter, such as turf taken from a rich field cut up into pieces by the spade, which is a very necessary precaution in the case of trees planted in what are called prepared borders.

“In filling in the soil, avoid the absurd, although very general practice, of moving the tree backwards and forwards to get the soil down among the roots. This I have called an absurd practice, for every pull you give the top draws the roots out of their places; and when the tree goes back into its proper place, the roots, being unable to push themselves back again, remain doubled up under the tree, thus thwarting the object you had in view, of spreading the roots carefully out at the commencement.”—MIDDLEMAS in *Magazine of Botany*.

In planting fruit-trees where the subsoil is of indifferent quality, it is advisable to place under each a piece of pavement 3 feet square and about a foot or 15 inches under the surface, that the descending roots, when they come in contact with it, may be made to take a horizontal direction instead of a perpendicular one. This is one great means of keeping them near the surface, and has been found of much advantage in this respect, even when the soil is of the very best quality, and whether the bottom of the border has been concreted, vaulted, or resting on a drainage of broken stones or not. Where these improved modes have not been attended to, such pieces of pavement may be of larger size; and where the subsoil is wet, cold, or bad, they should be laid hollow underneath, that dryness may be secured. This is a practice of old standing, many of the oldest fruit-trees still existing in monastic gardens being found so provided. In planting where the ground has not been thoroughly prepared, instead of filling in the soil only taken from the pit, it is of advantage, after the rootlets are slightly covered with fine compost, or the best of that taken out of the hole, to break down the sides of the pit all around, and to use it also for working in amongst the roots, as by this means the size of the pit is increased, and the scope of loosened soil for the roots considerably extended. In planting rare or ornamental trees in parks, the surface turf should be broken down and placed in the bottom of the pit; and where it can be spared, a ring of turf should be taken off all around, and wrought up along with the soil used in covering the roots.

*Treading the soil about the roots of trees at transplanting* is a dangerous operation, more honoured in the breach than the observance. The soil should be carefully wrought in about the roots by the hand or with the end of a blunt stick; for the pressure of the foot, unless carefully applied, is apt to break off the principal roots unobserved.

*Manuring trees at transplanting.*—This is an old and barbarous custom, practised only by those who know nothing at all about the matter. Naturally rich and fresh loam is all the manure they require. Trees require manuring only when, by reason of old age, or by having exhausted the food natural to them within the range of their roots, they become exhausted from want of sufficient food.

*Mulching trees at transplanting* is an old but useful practice. It means covering the surface above where the roots are, immediately after planting, with light littersy matter—moss, decayed leaves, or the like—with a view to exclude

frost, or rather to prevent the escape of heat, and lessen the evaporation of the moisture from the soil, and hence to preserve the roots from suffering from drought. Mulehing with rich manure is injurious, unless in the case of vines or trees requiring greater stimulus than the soil affords.

*Shallow transplanting.*—Deep planting is one of the greatest evils to which trees, particularly fruit-bearing ones, are subject. No tree should be planted deeper than it formerly grew, as its roots are stifled from the want of air, or starved by the poverty of the soil at the depth at which they are placed. It is much the better and more natural process, in fact, to plant the tree so that it shall, when the whole is complete, appear just as deep as before, but standing on a little mound 2 or 3 inches higher than the level of the ground about. This, when the ground settles, will leave it nearly level with the previous surface. "I advise," says Harrison, "that the roots of fruit trees against a wall be not planted more than 6 inches deep, and plant nearer the surface than 6 inches in wet heavy soils, and deeper in those that are lighter."

"Nothing is more common than too deep planting, and the temptation to it is greater, because deep-planted plants, from having their roots more accessible to moisture, are more certain of growing the first year, and are less in want of mulching to exclude the heat and drought, and of staking to prevent them from being moved by the wind." Deep planting, by placing the roots almost beyond the reach of solar influence, retards the growth in spring, and continues it so late in autumn that the wood and buds are seldom properly ripened: therefore in cold and wet climates deep planting should be avoided, as tending greatly to increase the evils such climates are known to possess. There are some plants of a herbaceous character which do not suffer from deep planting, of which the horse-radish may be given as an example; the majority, however, do suffer, and shrubs and trees in an especial degree. This fact, although long known, appears never to have been physiologically or satisfactorily explained. In tracing the analogy which exists between vegetables and animals, the evil of deep planting has its counterpart in the injury that may be inflicted upon the latter by wantonly or accidentally causing damage to be done their most vital parts. All vertebrate animals may be deprived of existence, if serious injury be done to that part at the back of the neck between the spinal marrow and the brain; and the same fatal consequences will follow in a plant if injured at that part which connects the root and stem, which is the part of all others the most susceptible to injury, and is called the *neck* or *collar* of the plant. If a seedling plant be cut over at that point, the root immediately dies; but when a tree and most herbaceous plants have attained a certain age, this is less likely to happen, in consequence of their being then furnished at that point with adventitious buds, which, should the tree be cut over, are called into action, and throw up shoots or suckers; but if the collar be cut through, no such action can take place. Deep

planting produces a similar fatal result, although not so instantaneously; and hence the unhealthy and ultimate death of all trees either planted too deep or having earth heaped over the roots, and thus burying the collar or vital part. This part also is so sensitive as to be more readily injured by cold than any other part of the plant; hence the necessity of protecting half-hardy plants by covering it during winter. To this reference will be often made in speaking of the protection of half-hardy plants, trees, and shrubs.

*Transplanting on raised hillocks.*—Many excellent cultivators, with a view to keep the roots of their trees, more especially fruit-bearing ones, near the surface, that they may be within the reach of solar influence, and often to prevent their entering into a bad subsoil, plant on raised mounds or hillocks. In this, so far as fruit trees are concerned, and also where the soil is damp naturally, or rendered so by a wet climate, they do well, because it is the most economical way of finding a good substitute for a bad soil, and in many situations it is wise to have recourse to it. This need not, however, be carried any further than to set the roots upon the natural level of the surface, covering them sufficiently with good soil, which will, for all ordinary purposes, be found sufficient.

No man has had greater experience, or has succeeded better, in the removal of trees, than Mr Barron of Elveston. On the advantages of mound or hillock planting he says, in "The British Winter Garden," p. 37—"Much advantage would be gained in every way by placing the tree on the surface of the ground, and by adding soil for the roots to be planted in. By this means the roots, instead of being cramped in a pit, and arriving speedily at the subsoil, have the depth of the natural soil to sport in, besides the free access of the air (so essential) being secured. The trees, when planted, have on this plan the appearance of being placed on raised bases, and in this way height is gained." This opinion is founded on sound practical experience. The physiological reasoning by Dr Lindley, in "Introduction to Botany," vol. ii. p. 181, given below, confirms the above, and proves to us the advantage of mound planting, by reason of its enabling us to add with so little trouble to the extent of the pasturage of the roots, if the object aimed at be bulk of timber or size of shrub, as well as circumscribing the range of the roots, keeping them from penetrating a bad subsoil, and above all elevating the temperature around them, if the object be healthy and productive fruit-trees. "It is generally believed that roots increase *only* by their extremities, and that, once formed, they never undergo any subsequent elongation. This was first noticed by Duhamel. Variations in this experiment, which has also been repeated by Knight, produced the same result; and the whole phenomena appears to be one of those beautiful evidences of design which are so common in the vegetable kingdom. If plants, growing in a medium of unequal resistance, lengthened by an extension of their whole surface, the nature of the medium in which they grow

would be in most cases such as the mere force of their elongation would be unable to overcome; and the consequence would be, that they would have a twisted, knotted form, that would be unfavourable to the rapid transmission of fluid, which is their peculiar office. Lengthening, however, only at the extremities, and then by the continual formation of new matter at their advancing point, they insinuate themselves with the greatest facility between the crevices of the soil. Once insinuated, the force of horizontal expansion speedily enlarges the cavity; and if they encounter any obstacle which is absolutely insurmountable, they simply stop, cease growing in that particular direction, and follow the surface of opposing matter, till they again find themselves in a soft medium."

*Replanting the ground formerly occupied with trees.*—Never plant trees in the same spot where an old tree stood before, as the ground has become exhausted of that very food upon which only the young tree would have to depend for its support. The ground, however, in such cases as that of wall-tree borders, may be removed, and fresh soil brought to replace it. Other reasons have also been assigned for this, the principal of which are those of Brugmans and Maicaire, who believed that the roots of plants return a portion of their peculiar secretions back again into the soil. More recent and more satisfactory experiments have not strengthened their opinions, but so far reversed them, that the root secretions are now regarded as unimportant, if not altogether apocryphal, except in cases where the roots have been wounded.

*Supporting trees after transplanting.*—This is an important operation, and deserves much more attention than has hitherto been paid to the subject. When a tree or shrub is removed to a new place, the operation of lifting, be it ever so carefully done, destroys many of the extreme points of the roots, all of which act as subterranean *guy*s, maintaining the tree in an upright position, and resisting the severest gales that blow. They in this case exemplify one of those many and wonderful provisions made by the Creator of all that is good and perfect, even in the economy of the vegetable kingdom. The roots here perform a compound office—they collect and prepare the necessary food for the plant, and at the same time, by their united strength, support it in that position in which only it could exist. These supports, therefore, being cut off, artificial ones must be provided, until the trees are re-established again. In planting fruit trees against walls, the branches should be immediately attached to them, to prevent their being broken, or the bark injured by friction (the necessary pruning to be attended to in spring). Standard trees of whatever size, as well as shrubs, demand attention in this respect, as they are more exposed to the action of the wind. If they are small, single stakes will be sufficient; but if large, stronger poles, and of greater length, will be required, and these should be placed in a triangular form, let into the ground at a proper distance from the roots, and brought together at the tops, in such a way and at such a point as shall best act by their oppos-

ing resistance in maintaining the perpendicular position of the tree. Care must, however, be taken that a collar of some elastic or soft material, such as straw, shavings, moss, gutta-percha, &c., be placed at the point of pressure, to prevent the bark being injured by friction, or indeed extreme pressure during high winds.

There are many ways of supporting newly-transplanted trees and shrubs. Some make use of strong wire made fast to them at a considerable height, and fastened to stout pegs driven into the ground, forming with the surface an angle of 45°; while others use cords or ropes of various strengths, according to the size and exposure of the trees. No doubt either of the latter are more light and elegant, so far as appearance goes, and therefore well fitted for use in the ornamental parts of the grounds, but neither are so strong or so steady in their support as larch or other poles set against them in a triangular form. The injury done to newly-transplanted trees, for want of such precautions, is very great: the strain upon the roots is considerable, and in spring, when our severe winds occur, the first efforts made by them in the formation of new roots are often completely destroyed; and from the constant waving about of the head of an unsupported tree, a cavity is formed in the soil at the base of the stems, which, increasing in size, admits both water and too much air to the roots, both of which are injurious to them; but the great mischief is the derangement of the roots.

*Change of climate injurious to newly-transplanted trees.*—Much of the want of success in forming new plantations arises from the circumstance of the sudden transition from the climate of a snug well-sheltered nursery to the open bleak exposure of an open park or unsheltered plain. "The comparatively dry state of the atmosphere in the latter is not the least prominent source of the injury. Wherever vegetation is scanty, there will the atmosphere be deficient in moisture—a subject of great importance, when considered in relation to the progress of young trees. And as vegetation not only participates in the benefits, but materially augments the atmospheric moisture of a district, it follows that, by employing other trees as shelter to those we are most solicitous about, we combine several essentials to success—viz., breaking the force of the winds, affording a gentle shelter, and condensing and retaining a large amount of moisture."—*Hints on Planting Ornamental Trees*, &c., p. 12. The same effects apply to transplanting trees of any size from thickly-planted woods, and placing them as single specimens or in small groups in open parks, exposed to more air, cold, and evaporation than in the atmosphere in which they were accustomed to grow. This is a prevalent source of failure in transplanting, and seldom attributed to the real cause.

*Some trees are more difficult to transplant than others.*—Of fruit-bearing trees, the cherry, particularly when large, is the least successfully removed; and next to that the apricot, nectarine, peach, pear, apple, and quince, their facility in transplanting being in the order in which we have placed them. Of ornamental trees and

shrubs, the whole order of Conifers, the Almond, Broom, Aralia, Arbutus, Baccharis, Birch, Beech, Caragana, Cistus, Colutea, Cratægus, Cytisus, Genista, Holly, with the whole genus Ilex, the Juniper, Lonicera, Mespilus, Mulberry, Phyllæra, Pyracantha, Quercus, Rhus, Rosa, Robinia, Sweet Bay, Ulex, Walnut, &c., are much less impatient of transplanting when of a large size than are the Poplar, Willow, Alder, Ash, Azalea, Rhododendron, Kalmia, Ledum, Aucuba, Ligustrum, Buxus, Portugal and common Laurel, Cornus, Tilia, Syringa, Ribes, Spiræa, Laurustinus, &c. &c. American plants in general transplant well, on account of their numerous fine hair-like roots, which cause the soil to adhere to them in large masses. Without balls, however, they would rank amongst the most difficult of all. Plants with long tap-roots, with few fibres, are very difficult to move; and others whose soft spongy roots, when broken or cut, do not readily heal, are equally so.

*The proper size for transplanting.*—This varies with the sort of tree as well as with its age. It is, however, a maxim settled both amongst theorists and practical men, that health, immediate vigour, and duration, are all greatly promoted by transplanting all trees of a small size, as well as while they are comparatively young. It often happens, however, from a variety of causes, that large trees must be transplanted to attain certain ends. This indeed may be done, and is done, but the success depends much on the way the operation has been performed. But transplanting large trees, even with the greatest care and judgment, affects them more or less, and a long period of rest or feeble growth must be expected to follow; while in planting young trees, they commence a vigorous state of growth, and often attain a great size long before the large trees have fairly arrived again at a healthy condition. "The small tree, transplanted with its system of roots and branches entire, suffers little or no check; the older and larger tree, losing part of its roots, requires several years to resume its former vigour. The constitution of the smaller tree is healthy and unimpaired, that of the large is frequently enfeebled."—**DOWNING.**

The first successful attempt at removing very large trees of which we have any certain knowledge, was that of the Duke of Saxo-Coburg, the grandfather of His Royal Highness Prince Albert, who transplanted chestnut trees of 30 or 40 feet in height. Capability Brown, Sir Henry Steuart, and others in our own country, have since performed great feats in this way; but by far the most successful transplanters of trees of extraordinary dimensions is certainly Mr Barron of Elveston near Derby. In his recently published work, "The British Winter Garden," he informs us that his first attempt in this way was upon three cedars of Lebanon, "varying in height from 28 to 35 feet, and the diameter of their branches from 25 to 30 feet, with trunks varying from 3 to 4 feet in circumference." That these trees suffered not by removal is evident from the following table of dimensions, taken when transplanted, and again in 1852:—

Height of trees in 1831.	Circumference of trunk in 1831.	Height of same trees in 1852.	Circumference of trunks in 1852.
28 feet	4 feet	46 feet	6 feet 1 in.
32 "	3 "	55 " 6 in.	6 " 3 "
35 "	3 "	58 " 6 "	6 "

"The success," Mr Barron observes, "which attended these operations, led to a holder attempt the following November. A large cedar of Lebanon, measuring in height 33 feet, diameter of branches 48 feet, and circumference of stem (one foot from the ground) 6 feet, was removed to the distance of between two and three hundred yards; and with due attention to both branch and root watering the following summer, the result was satisfactory, as its comparative dimensions now show: viz., when planted in 1831 its height was 33 feet, and circumference of stem 6 feet; it is now (1852) 44 feet in height, and 7 feet 10 inches in girth of stem. Yews of a very large size, some of which are supposed to have been several centuries old when purchased by the late Earl of Harrington, have been removed a distance of 10, 12, and 25 miles. The dimensions of two of them are given by Mr Barron as follows: First, "Trunk at 3 feet from the ground, 7 feet 3 inches in circumference; height 33 feet." Second, "An old yew, which forms an arbour 14 feet 2 inches high, and 59 feet 9 inches in circumference" round the branches, the girth of the trunk being 7 feet 4 inches. These are perhaps the oldest if not the largest trees that have ever been successfully transplanted in the world.

In planting fruit trees most judicious gardeners prefer what are called maiden fruit-trees—that is, one year after being grafted—while others prefer trees two years from the graft. Much, however, here depends on the kind of tree and the mode of training to be adopted. Fruit trees of greater age are often planted—indeed, when coming into a bearing state, such trees will produce fruit sooner; but there can be no doubt, taking into consideration health, duration, and the ease with which a maiden or even a one-year-trained tree can be made to grow into any form, that either of these is preferable. Fruit trees, however, like all others, may be successfully transplanted almost of any age and size, if the requisite precautions be taken.

*Preparing trees for transplanting.*—Trees or shrubs taken from the nursery in a young state require no other preparation beyond being carefully taken out of the ground with their roots as little curtailed or injured as possible. The case is wholly different when trees or shrubs of a large size and age are to be transferred from one place to another. The late Sir Henry Steuart wrote a whole book almost upon this subject, without, it would appear, having been aware that the very rules he endeavoured to inculcate as new had been practised for more than a century before. The whole rationale of the system consists in shortening the leading roots at a proper distance from the stem, which distance must ever be governed by the size of the tree to be operated upon; and this is done

by digging a trench round the whole mass of roots, undermining them, and cutting off all the roots projecting beyond this line. "The trench should be dug at such a distance from the tree as will include all the large and sufficient ball of roots; and it should be done in the spring, or before midsummer, when it is desirable to remove the tree next year. After all the roots that extend to this circular trench are cut off, the earth is replaced, and the season following an abundance of small fibres is sent out by the amputated roots, which, when the whole is now removed, will insure the success and speedy growth of the tree. This is more completely the case when the tree is prepared two years before transplanting. A variation of this mode, which has been found quite as successful and less laborious, consists in leaving the trench open, and covering it with boards only, or boards and a top layer of turf. The tree is then somewhat checked in its growth, it throws out an abundance of small fibres into the ball of earth containing the roots, and is the next season transplanted with great ease and safety."—**DOWNING.**

If the air is prevented from reaching the roots by a sufficient covering being placed over this trench, there can be no doubt but that this latter mode is to be preferred.

When prepared compost, as recommended by some, or even the natural soil of the place, is thrown again into trenches thus formed, the certain consequences are, that the young fibres and still more delicate spongioles will form themselves in this soft and easily-penetrated medium, and consequently when the removal takes place, notwithstanding all the care that may be bestowed during the operation, those important organs are more or less injured or destroyed—in fact, placing the tree in about the very same condition that it would be had it been removed the preceding season, when the cutting of the roots took place. Those who advocate this plan, and profess to have studied its effects so closely, must surely have observed the condition of the spongiolets upon opening the trench at the period of the intended removal. Leaving the trench empty, and covering it over to partially exclude the air, as recommended by Downing, must certainly be considered of the two modes the most likely to be of advantage to the tree. And when the trench is opened, if the earth of the ball intended to be left were carefully removed from around the roots to be amputated, and were they cut back a few inches within the circumference of the ball, the young fibres and spongiolets would form within it, instead of without it, and at the time of removal would be very considerably protected. Mr Barron, although apparently a convert to Sir Henry Stewart's mode of preparation in early life, set it afterwards entirely aside, and chalked out a course of his own, the success of which has been sufficiently demonstrated. He says, in "The British Winter Garden," p. 27: "The thought occurred to me that if it were possible to remove a tree with a large mass of earth, something similar to that containing the roots after Sir Henry Stewart's pre-

paration, I should be stealing a march upon him, and be as forward at once as he would be in two years.

"I then set about conquering the mechanical difficulty, which, when once accomplished, I saw that success would be certain, and many of those mystified physiological difficulties removed to which Sir Henry Stewart seemed to attach so much importance, and which, if not properly understood, would result in failure." Mr B. remarks that he would have been glad to have brought to bear upon the undertaking which he had encountered any portion of Sir Henry's system, but this he found impracticable. Having constructed his machine, which will be afterwards noticed, he proceeded in manner following to prepare a tree for removal: "A tree being about to be lifted, say from 40 to 50 feet high, the diameter of the branches being of the same dimensions, the groundwork operations would commence on the outside of a circle of from 20 to 25 feet in diameter, more or less, judging from the kind of tree how far the roots would extend horizontally; the soil would be then cleared from the roots, carefully preserving every fibre, as far as practicable, up to within a given space of the stem, where the remaining mass of earth and roots must be left undisturbed." Mr B. deviates from general practice in forming his ball nearly a parallelogram instead of a circle; and for such a tree as that noticed above, the dimensions of the ball are 9 feet 6 inches by 8 feet. During the operation of removing the earth from amongst the roots, the greatest care is taken that none of the roots that extend beyond the ball of earth be in any way injured, for on their preservation so much of the success of the plan depends. The rationale of Mr Barron's principle amounts to this, that instead of cutting the roots two years before planting, with a view to cause them to send out numerous fibres and spongiolets, many of which will inevitably be destroyed at removal, and have to be replaced by others before the tree can be supplied with its requisite amount of food, he removes at once, preserving the roots as much as possible, and allowing them to form new fibres and spongiolets in the place where they are to remain undisturbed. By his process, also, he reduces the weight of the ball of earth considerably, and hence renders the transport more easy. Heavy balls must have an immense strain on the roots, however carefully the operation may be performed; and the injury roots sustain from this alone, but which is not discernible to the eye, is more than is generally supposed, and in many cases more than even the loss of a portion of the roots. Some erroneously suppose that by shortening the extremities of the roots they form multitudes of others within the ball, throwing them out laterally from their sides. Such is not the case, for roots elongate only from their points; so that, in fact, after a time, no food-collecting roots exist for a considerable distance from around the stem of the tree, as they are always extending in a direction from it.

Shortening the roots, as recommended by Sir Henry Stewart and others, would be of advan-

tage, if, after the ball was formed and the roots cut, it was enclosed within a casing of very strong planking, or staves strongly hooped round, and a few inches larger than the size of the ball, to admit of fine fresh mould being rammed in all round for the fibres and spongioles to form in for a season. Trees so prepared might be very safely removed almost at any period; and when set in their new situations and the casing removed, the roots would extend in quest of nourishment in the surrounding soil, and bear their removal without injury.

Could the roots be secured in any way, there is no fear of removal in these days of improved mechanical appliances, so far as mere weight is concerned. But there are other considerations to be kept in view, of which the situation the tree to be removed is placed in, the condition of the ground, which is in general too soft to sustain heavy carriages, the obstacles which bridges under railways, tunnels, acute turnings in rides, drives, the branches of other trees, &c., present, have all to be taken into consideration, all of which present serious obstacles to the transplantation of large trees. With trees standing isolated in an open park the case is very different, and it is those, and such as grow on the outskirts of plantations, that the planter should choose for his experiments in gigantic transplantation.

*Thinning the branches at the time of removing large trees.*—In planting large trees whose heads are crowded with branches, it will be expedient to partially thin them; the quantity of branches to be removed will partly depend on the nature of the tree and the intention of the planter. The beech and the hornbeam are impatient of pruning when transplanted, and have been known to be killed by an injudicious use of the knife; other trees, such as the yew, holly, lime, elm, and all the Acer tribe, require little pruning at planting, because they have an abundant supply of fibres around and near the main stem. Apple and pear trees, if of a large size, are improved by a moderate curtailment of their branches. The intention of thinning the tops of trees during this operation is twofold; first, it prevents the wind from having too much effect upon them; and, secondly and principally, it lessens the draught upon the roots, by lessening transpiration by a superabundance of leaves, and reduces them to the amount of moisture which can be absorbed by the roots, which as yet are diminished in number and action.

*Transplanting from pots.*—Many rare trees and shrubs are grown in pots in nurseries, to render them more portable, and better fitted for transportation to a distance. Of these, most of the rare Conifers, Arbutus, red cedars, junipers, the rarer species of oaks, &c., may be given as examples. The circumscribed space allotted to the roots within the narrow limits of a pot from 5 to 9 inches in diameter, produce a tendency in them, for want of room to extend themselves horizontally, to assume a spiral form; the whole ball will also become a confused mass of roots, searching in all directions

for food. To turn plants so circumstanced out of the pots into pits ever so large, or into soil ever so well prepared, with their balls entire, and their roots in their constrained state, would be much the same, so far as the progress of the plant's growth is concerned, as if it continued to remain in the pot in which it had been growing. Such balls should be carefully broken up, but this ought to be done without the roots being broken during the operation. To facilitate this, if the balls be steeped in water, the soil will separate more freely; and indeed, in extreme cases, it will be well to wash the whole of the soil away, so that the roots may be carefully singled out and spread in their new bed in their natural position. When plants are kept too long in pots—and this is a case of very frequent occurrence—their roots become so tortuous that they cannot be straightened out, and this is the more difficult the older and stronger they are.

Mr Barron, in "The British Winter Garden," has clearly illustrated the evils of growing plants in pots intended to be afterwards planted out, and expected to become in time goodly trees. "The contorted form which the roots are compelled to take while imprisoned within the limits of a small pot, prevents the free passage of the sap food collected by the spongioles from reaching the stem in sufficient time and quantity to support the leaves and branches while they are exposed to the powerful action of solar heat, as well as the evaporating action of dry parching winds. The first consequence of this mistreatment in youth is sickliness and deformity, and afterwards premature death. This is very generally observable in *coniferous* plants, and of itself quite enough to account for the very few healthy cedars of Lebanon, for example, to be found in Britain of any age, and the multitudes of them which everywhere abound in a distorted, enfeebled, and diseased state. No plants which are expected to attain a large size should ever be grown in pots, but should be treated upon the same principle as our common forest trees, with this difference, that they never should be allowed to remain more

Fig. 129.

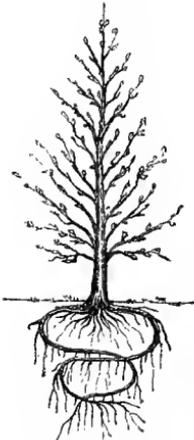

EXAMPLE OF WELL-FORMED ROOTS.

than two years, and in some instances not so much, without being transplanted. By this means the main roots would radiate from the common centre in a natural manner, and the roots become sufficiently numerous to insure a ball of earth to adhere to them. Plants would thus be furnished of a very superior quality, and at a much

cheaper rate than those mutilated and expensive deformities nurtured in pots."

Fig. 129 shows the state of the roots of a tree that has never been confined to the circumscribed limits of pot culture, fig. 130 that of one which has. In the former, the roots are extending in all directions near the surface in search of food; in the latter, their free produce has a direct tendency downwards, where they neither can derive food, nor, from their position, have the same effect as the former in maintaining the perpendicular position of the tree.

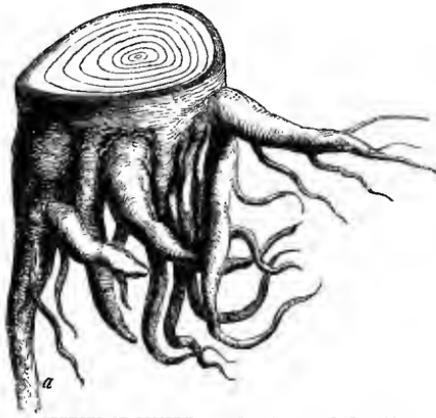

Fig. 130.

EFFECTS OF POT CULTURE ON ROOTS.

In such a condition, and much worse, will be found the roots of camellias, and other plants grown in pots, where care has not been taken at shifting to disentangle them, and afford them more space for their horizontal extension. Fig. 131 shows the state of a fruit or forest tree subjected in early life to pot culture; and the same effect will be produced on the roots of many trees when planted in pits

Fig. 131.

EFFECTS OF COMPRESSED ROOTS ON WOOD, ETC.

with their sides walled round with undisturbed soil, as referred to page 358, when speaking of the necessity of preparing the soil previous to planting. In fig. 131 it will be seen that, where the roots have been most confined and contorted, the supply of sap thrown into the side of the tree immediately above them has been limited and irregular, as seen by the smaller and irregular portions of the annular rings in the transverse section of the trunk; whereas, again, where the root *a* has had the means of penetrating deeper into the soil, and consequently been enabled to collect a greater amount

of sap food, the annular rings above it are larger and more uniform in size.

*Transplanting fruit trees with a view to correct over-luxuriancy of growth, and to induce them to form blossom-buds.*—This operation may be regarded as a species of root-pruning, and the effects will be found to be similar. Taking up a tree entirely enables the operator not only to regulate the state of the roots better than merely root-pruning, as usually performed, but it also enables him to bring the roots nearer to the surface, should they have been over-deep before, and also affords an excellent opportunity of removing the exhausted or bad subsoil, replacing it with better, or of draining or vaulting under it, if deemed necessary. Root-pruning and taking up and replanting are the very opposites to severe branch-pruning. All fruit trees may be thus treated with much advantage, and those which, by reason of their great age, have ceased to bear fruit, and even make little or no wood, in consequence of the flow of the sap becoming sluggish, will, when root-pruned and replanted in fresh soil, assume a renewed vigour, become fruitful and healthy. We lately saw two apricot trees which had been planted thirty years, and had ceased to produce fruit, and appeared to be in the last stage of decay; by being taken up and replanted in fresh soil, they became as vigorous and productive as they were when only twelve years old.—(Vide *Root-pruning*.)

Taking up and replanting fruit trees, without any curtailment of their roots beyond those that may be broken or injured during the operation, is somewhat different from mere root-pruning, both in the operation and in its effects. The intention in the latter case is a curtailment of the stronger roots, which are known to be the chief collectors of crude and superabundant food, which for the most part goes to the formation of coarse watery shoots, themselves the very emblems of sterility. The lifting and replanting process affects this also, and besides, if performed every two or three years, according to the state of the trees, brings about a state of productiveness in them, by transforming the coarse, watery, barren shoots into short, firm, well-matured wood, fully set with flower-buds. Another advantage attends the lifting process, which root-pruning does not so completely effect: the trees are prevented in spring from pushing too early, as the food is longer of being collected, and hence the ascent of the sap is proportionably delayed. We all know that the later in spring vegetation is excited, the greater chance there is of the blossoms escaping our destructive late spring frosts, and the greater will be the chance of a good set of fruit. Mr Marnock, in referring to this process, observes: "But this is not all; for just as the greatest demand is being made upon the tree by the swelling and ripening of the fruit, the roots are becoming stronger and more numerous, and entering into the recently disturbed, and it may be new earth. They are in this way enabled to swell off and ripen the fruit in a manner superior to what they would if merely root-pruned or not lifted at all. It is not difficult," he

continues, "to believe the effects which new maiden soil would be likely to have in such cases; for it must be remembered that trees thus accustomed to be lifted do not become unhealthy, the roots being all carefully tied and relaid in newly prepared fresh loam."

*Transplanting coniferous plants.*—These for the most part do not affect a deep or rich soil; the thin soils formed over primitive formations appear to be their natural element. Some, however, seem to luxuriate more than others in deeper soils, such as a few of the *Abies* tribe; but although we find them occasionally indigenous in such soils, we do not find that they avail themselves greatly of them, as their roots for the most part spread out horizontally very little under the surface. In cultivation, however, they do not refuse to thrive in soils of medium quality and of considerable depth; but in one thing they seem to have a choice—namely, a new soil which has not been long, if at all, under cultivation. The season of transplanting has usually extended, as in the case of deciduous trees, throughout the later end of autumn, all winter, and the early part of spring. We believe, for ordinary purposes, those seasons may be all very well; but for the removal of coniferous plants of great value and rarity we would decidedly prefer the month of June, when the young shoots had made considerable progress. Mr Barron moved spruce firs in June from 30 to 40 feet in height. We have ourselves removed many rare and valuable conifera during June, and would, from our previous success, do so again at that time rather than at any other. There has, in general, been a kind of dread in the minds of cultivators in transplanting coniferous plants, particularly when they have attained some age and size. We see no more difficulty in doing so in their case than in that of any deciduous tree whatever. All depends on performing the operation properly, and choosing a right season.

One of the greatest evils in planting the rarer coniferous plants is the absurd practice persisted in of choosing plants grown in the nurseries in pots. A greater mistake cannot be fallen into. It imposes an unnecessary expense on the nurseryman which the purchaser has in general to pay, while he also receives a very inferior article for his money. Nurserymen, in nine cases out of ten, receive orders for coniferous plants accompanied with positive instructions that if the plants are not *in pots*, on no account are they to be sent. There are few nurserymen nowadays but are aware of the absurdity of this, but they have no choice. With some of their customers they may remonstrate, and point out how much more it would be to their advantage to have plants *out of pots*; with others they cannot do so—for in plant buying, as in everything else, there are people who pride themselves on fancying they know the value of the article sold better than the seller himself. But let a nurseryman speak for himself: "A prejudice exists against plants removed from the open border; in numerous instances it is a just one. It has arisen from the fact that many growers do not transplant often enough. The consequences are

the plants become coarse-rooted, and, being removed in an indifferent condition, are often lost before they can recover the check consequent on their change of situation. But the remedy for this is in the hands of the purchasers; if coarse-rooted plants cannot be sold, growers will cease to bring them into the market. But the disadvantages of pot-grown plants are, as a general rule, of equal magnitude with the worst condition of those badly managed in the open borders; yet purchasers patronise the former to a large extent, and to the exclusion, in a great measure, of the latter. As it becomes a matter of great importance to nurserymen that their stock of pot-grown plants should occupy as small a space as possible, pot-bound specimens are the rule rather than the exception. And for plants intended to be removed to the open ground as permanent specimens, scarcely a worse condition could exist: it is superlatively bad." This quotation is so truly practical that we are inclined to give it at length. "For the purpose of illustration, we will suppose a person to have purchased a plant in the condition above described, and intends immediately to plant it out. On removing the pot, he is delighted to find coil upon coil of fine healthy roots. He knows very well that to commit them to their new situation in an uncoiled state will be highly improper, and so, with great care, he proceeds to disentangle them. However careful he may be, the loss of many valuable roots will result, and damage to the remainder will be equally certain. Those in the interior of the ball, from their size and woody texture, will not yield at all; and he closes his half-finished labour with the conviction that he has seriously damaged his plant. But this mutilation, great as it is, is far preferable to having planted it with its matted roots undisturbed. A plant which has once been thoroughly pot-bound never gets so firm a hold on the soil as one whose roots have never been confined. Instances are numerous where valuable specimens, after years of growth, have been blown down in consequence of the very slight manner in which they retained their position. The main roots, when young, had from pot culture acquired a coil-like arrangement, which during all their subsequent growth they adhered to—enlarging, but not spreading—increasing in bulk, but contributing little to the mechanical support of the tree: in fact, they often destroy each other; and in every instance of a plant which in its young state has been subject to the confinement of a pot, these conditions will be evident."—*Hints on Planting Ornamental Trees, &c.*, p. 311, by STANDISH and NOBLE. Plants also grown for several years in pots become, from sheer starvation, debilitated in constitution, deformed in structure, and rarely, if ever, even should the roots become untrammelled, assume the same portly appearance as those whose roots have not been subjected to the same restraint.

*Transplanting evergreens.*—Regarding the best season for performing this operation opinions are greatly divided. We have removed evergreens at all seasons with apparently equal success. The late excellent Mr M'Nab, in his

"Treatise on transplanting Evergreens," says: "Evergreens may be planted with much greater safety in *mild weather in autumn or winter, than at any other period of the year.*" Another authority remarks that evergreens may be transplanted in autumn, or at any time in open moist weather during autumn, winter, or early spring. In dry or frosty weather it is always dangerous to remove them, because the sap in an evergreen is more or less in motion at every season of the year, and the plant is never so completely dormant as deciduous trees are. In regard to the season of performing the operation, we have the following reasoning by Mr Glendinning, in the "Journal of the Horticultural Society of London," vol. iv. p. 41: "This I consider to be a much more important matter than many seem to imagine. The winter months—that is, from the end of October to the beginning of April—have been generally recommended; indeed, almost universally so. From these opinions I *entirely dissent*, how eminent soever the authorities may be who have laid them down. I quite admit that a qualified success may have attended their operations; but I deny, independently of this, that it is the right season for the execution of such work, and the slightest acquaintance with vegetable physiology will conclusively demonstrate the truth of this assertion. Let it be clearly understood that I am alluding to plants of from 6 to 30 feet and upwards in height, and not to mere nursery stock," which are frequently removed to keep them in a transportable state. Mr Glendinning, passing over the details of the ascent and descent of the fluids in plants, and the formation and deposition annually of new wood in all ligneous vegetation, proceeds: "It will be sufficient for my purpose to state that this extension and formation takes place chiefly after midsummer, and principally in evergreens during autumn, when the young shoots begin to attain a certain degree of consistency. It is during this downward tendency of the fluids, and when the solar action is in some measure on the decline, that I should seize and conduct with all rapidity the operations of transplanting; and if this is intended to be conducted extensively, I should recommend the end of August as a good time to begin, September being the *safest* month in the year, selecting such plants to commence with as have matured their shoots. Another and very important reason remains to be stated why autumn is to be preferred, for undertakings of this kind, in preference to winter. The force of the sun during summer, although now on the decline, has warmed the earth to a considerable degree and depth, so that the mutilated roots are comparatively situated on a gentle bottom-heat, which rapidly promotes cicatrization, and frequently aids the emission of young spongiolets during the current autumn. The season which I have here ventured to urge for the performance of the work under consideration as undeniably theoretically the right period, appears beyond all question; and being no mean experimentalist in rural embellishment with plants of considerable magnitude, I can attest also that it is practically the season to be preferred be-

yond all others. I had occasion to superintend the removal of upwards of two thousand trees and shrubs, all evergreens, and varying in size from 6 to 40 feet high, during one autumn." The trees were prepared by cutting in the roots the previous spring, "and as the undertaking was rather gigantic, the work was begun in August, and finished with the year. The result was, of course, watched with some interest; and the following summer, when an examination took place, I found that those trees which were transplanted early in the season indicated little change from their removal; but the contrary was the case with those which had undergone similar transplantation during December. In fact, the gradual diminution of the motion of the sap, accompanied with declining atmospheric action, which tended, in conjunction with the usual autumnal precipitations, to cool and saturate the earth, clearly and progressively exhibited our comparative success. The exact period to commence these operations must be determined by the nature of the season, and the state of maturity the current year's growth has attained. In some seasons an earlier beginning may be made than in others; some kinds of plants also ripen their wood much earlier than others: these, therefore, should receive the earliest attention. In hot and dry autumns the foliage of some of the larger specimens of certain species and varieties, especially such as have large and succulent leaves, will flag and droop. To guard against any injury arising from this, it will be advisable to well water the roots at planting—not with cold water from the well, but from the pond, where it has been exposed to the sun. With specimens of great rarity and value it would amply repay the additional trouble to occasionally syringe the foliage in the evening for a short period after planting. This, however, will not be required should the weather be cloudy or moist." Here we have not only good practical rules laid down, but physiological reasons given for them. In Mr Glendinning's views we quite concur as to the season of planting. It happens, however, unfortunately, that at this particular period, August and September, our flower-gardens and dressed grounds are expected to be in the highest state of keeping, because it is at that time that proprietors most generally reside at their country residences. The necessary confusion caused by the removal of a great number of evergreens at that time would be highly inconvenient. This, however, does not affect the principle of the reasoning given above; nor should it make us lose the opportunity of transplanting evergreens in woods and plantations, and in these cases the proper season should not be lost sight of; and again, if the operation is to be carried out upon a large scale, it is much better even to sacrifice the appearance of the grounds for one autumn than to lose the chance of a favourable time for performing the operation.

The formation of roots is the first effort of every tree after transplanting; and hence the importance of August, September, or October planting, because there is sufficient solar heat in the soil to aid them in this effort, which

there would not be during the winter months, but which is beginning again to be the case in April. "Add to this, that about the end of April and the beginning of May, we have frequently warm showers, which, to shrubs of this description, are extremely beneficial, and are always much better for vegetation than water, however well it may be artificially applied. The reason assigned for planting evergreens in August and September is, that they have made their shoots, and, if carefully done, will make fresh roots and become tolerably established before winter. Experience proves these seasons to be the best for transplanting these plants, and upon an extensive scale, and in exposed situations, we would advise the adoption of it. At the same time, circumstances may warrant their removal at almost any day in the year. Evergreens are extremely fond of shelter and of moderate shade; and it is probably the want of these that is the principal cause of the failure of these plants when removed at seasons when there is a long continuance of cutting winds, without any rain. In our practice at Stratton Park [Hampshire] we implanted 50,000 evergreens in one season, beginning in November and ending in February. Circumstances led to our planting at this season. The soil, for the most part, was of a strong clayey nature, and by no means favourable for plants in general; still, the success here was complete, inasmuch as out of that number not 200 plants died. The plants were brought a distance of twenty miles, and were from 2 to 3 feet high. We attribute the success in this instance to the shade which the plants enjoyed in summer and the shelter during the first winter after planting, as they were planted partly in very old plantations and partly in young ones, in both cases well sheltered and shaded."

The majority of sensible planters prefer the months of April, May, September, October, and November for transplanting evergreens, and this latitude is given because one month, from the state of the weather, may be better one year than in another. The ground temperature, in properly drained soil—say in the vicinity of London—is calculated to be in November 47°, and this is a very good root temperature for such plants to be placed in, and in such they will speedily strike root, which is the great object to secure.

Of all trees and shrubs requiring support from the effects of wind, &c., none require it more than evergreens that have been recently transplanted, as they present so large a surface of foliage at all seasons, and are consequently more liable to constant oscillation than those that are deciduous. When this is not guarded against, the young roots are prevented from taking hold of the soil around them, and the ball which accompanied them becomes separated from the surrounding earth; interstices are formed, into which rain first and frost afterwards enters, both equally injurious to the young and tender fibres; while in spring the parching winds would penetrate and prove equally injurious: they therefore require particular attention in this respect. Many

modes have been recommended, but the particular mode is of far less consequence than that it is properly done by one or other; for much of the success of transplanting depends on this being effectually accomplished.

Next in importance to supporting evergreens after transplanting, is that of watering them; and if the operation be carried on late in spring or during summer, the equally important precaution of shading them, not only from the effects of bright sunshine, but also from the still more evaporating effects of dry, cold, cutting winds, should not be disregarded. It is not the quantity of water actually given a newly planted tree, but the way in which it is applied, that is the chief point to be considered. Indeed, we believe that more harm is done by excessive watering at the roots by some, than by a deficiency of it in others; and this the more so if the water is taken from wells, which, if not of more than ordinary depth, are always much colder than the soil surrounding the roots. River or pond water should be chosen, and that applied frequently, and in small quantities at a time. If large doses of cold spring water are applied to the roots of newly planted trees, the temperature of the soil is lowered, the vital energies of the roots are paralysed at the very time they require the utmost amount of excitement, to enable them to recover the injuries sustained during the process of removal by the rapid formation of new roots and spongioles, which is their first effort; and everything, therefore, to assist them in the formation of these should be carefully attended to. Indeed, it is by no means going too far to say, that it were far better to apply water at the roots under such circumstances at 100° than at 35°—a temperature by no means uncommon in spring water during winter and early spring. Syringing over the tops has a most beneficial effect upon all trees, particularly evergreen ones, and this should be applied two or three times during the day. Shading from the sun in bright days lessens the evaporation, which would otherwise be going on in the foliage; and shelter from drying winds not only counteracts this in an eminent degree, but also maintains an increased temperature around them; and increase of temperature to the foliage, although less exciting than at the roots, has much to do with the successful results of planting. The best shading for such purposes is thin canvass, called by manufacturers screen-cloth, because, while it breaks the force of the wind, it admits light in a modified form to the plants; for exclusion of light, at a period when every aid man has at his command should be given to afford increased excitement to the roots, would be as bad as leaving them exposed altogether. In giving water at the roots, it is of little use to pour it around the stem, although we every day see due preparation made for this, by the formation of basins scooped out of the soil, and close to the trunk of the tree: whereas, to be of any utility, whatever precaution is made for preventing the waste of water, it should be immediately over where the young roots and spongioles are forming, which will only be around the circumference of the ball removed,

where what is called the preparation system has been followed; or immediately above that zone in which the roots are placed when trees are either planted without balls altogether, or having their most important ones beyond the ball, if managed as recommended by Mr Barron.
